Objective: The effects of prolonged arteriovenous carbon dioxide removal on hemodynamics during severe respiratory failure were evaluated in adult sheep with severe smoke inhalation injury. **Methods:** Adult female sheep ($n = 6$, 33.8 ± 5.2 kg) were subjected to intratracheal cotton severe smoke insufflation to a mean carboxyhemoglobin level of $83\% \pm 3\%$. Twenty-four hours after injury, a low-resistance 2.5 m^2 membrane oxygenator was placed in a carotid-to-jugular pumpless arteriovenous shunt at unrestricted flow to allow complete carbon dioxide removal and reductions in ventilator support. Animals remained conscious, and heart rate, cardiac output, mean arterial pressure, and pulmonary arterial pressure were measured at baseline, after injury, and daily during support with the arteriovenous carbon dioxide removal circuit for 7 days. **Results:** All animals survived the study period. Carbon dioxide removal ranged from 99.7 ± 13.7 to 152.2 ± 16.2 ml/min, and five (83%) of the six animals were successfully weaned from the ventilator before day 7. During full support with the arteriovenous carbon dioxide removal circuit, shunt flow ranged from 1.24 ± 0.06 to 1.43 ± 0.08 L/min and accounted for $20.1\% \pm 1.4\%$ to $25.9\% \pm 2.4\%$ of cardiac output. No statistically significant changes in heart rate, cardiac output, mean arterial pressure, or pulmonary artery pressure were demonstrated over the study course despite the extracorporeal shunt flow. **Conclusions:** Arteriovenous carbon dioxide removal as a simplified means of extracorporeal gas exchange support is relatively safe without adverse hemodynamic effects or complications. (J Thorac Cardiovasc Surg 1997; 114:1107-14)

Despite advances in critical care, the adult respiratory distress syndrome (ARDS) still carries approximately a 50% mortality rate.^{1,2} Current therapy is supportive as clinicians apply mechanical ventilation to assist oxygenation and promote carbon dioxide (CO_2) excretion. Mechanical ventilation

has well-recognized sequelae to both the injured and noninjured portions of the lung during the obligatory gas exchange. Sustained high airway pressures, with the use of either pressure- or volume-controlled modes of ventilation, lead to pressure-associated permeability edema³ and histopathologic changes nearly indistinguishable from those seen in ARDS.⁴ Recent work suggests alveolar overdistention is mainly responsible for the damage.⁵ To reduce the high pressures and associated barotrauma/volutrauma, recent ventilator management strategies limit inflation pressures at the expense of an increase in systemic CO_2 levels. This technique, termed permissive hypercapnia, has recently been shown to reduce the incidence of barotrauma/volutrauma and improve survival in ARDS.⁶

The success of venoarterial extracorporeal membrane oxygenation,⁷ especially in the neonatal population, has led to a resurgence in the use of extracorporeal techniques in the treatment of ARDS in the pediatric and adult populations. The

concept of venovenous extracorporeal CO₂ removal to allow a reduction in ventilatory support and associated barotrauma/volutrauma was applied by Gattinoni and associates^{8,9} to provide total CO₂ extraction and satisfy systemic oxygenation requirements using apneic oxygenation.¹⁰ Both extracorporeal CO₂ removal and extracorporeal membrane oxygenation involve the use of an extracorporeal circuit and the attendant potential for related complications.¹¹ The intravenacaval oxygenator was developed by Mortensen¹² to eliminate the need for extracorporeal blood circulation and still provide gas exchange. However, the intravenacaval oxygenator was limited by surface area and could only remove approximately 30% of the metabolic CO₂ production.

To simplify the extracorporeal component and yet achieve adequate CO₂ removal, Barthelemy and colleagues¹³ combined a pumpless artery-to-vein shunt with a membrane oxygenator and the ventilator management technique of apneic oxygenation to satisfy all the gas exchange needs of a large animal for up to 24 hours. Subsequently Awad and colleagues¹⁴ demonstrated the feasibility of prolonged extracorporeal CO₂ removal (7 days) with the use of oxygenators designed for cardiopulmonary bypass interposed in an arteriovenous shunt in a healthy animal model without complications. Unfortunately, these studies were compromised by high circuit resistance (>30 mm Hg) to spontaneous arteriovenous blood flow, necessitating a mean arterial pressure greater than 110 mm Hg to achieve adequate flow for total CO₂ removal. Other arteriovenous CO₂ removal (AVCO₂R) studies have also been accompanied by hemodynamic instability.¹⁵

We recently developed an AVCO₂R circuit with use of a new low-resistance membrane oxygenator to provide total CO₂ removal in both healthy¹⁶ and injured¹⁷ sheep models of severe respiratory failure. Total CO₂ removal could be achieved with significant reductions in minute ventilation and peak inspiratory pressures. In these studies, AVCO₂R circuit flow was up to 1.4 to 1.6 L/min, representing approximately 20% to 29% of the animals' spontaneous cardiac output with a circuit resistance less than 10 mm Hg. Although an arteriovenous shunt up to 29% cardiac output allowed a reduction in mechanical ventilatory support to approximately 16% of the baseline requirements, the long-term impact on hemodynamic function during ARDS remains unknown. In the present study, we subjected adult sheep to a severe smoke inhalation

injury to induce ARDS, then applied AVCO₂R at sufficient shunt flow for total CO₂ removal to evaluate the effect of sustained AVCO₂R flow on critical hemodynamic variables over 7 days. This investigation was necessary before our anticipated adult and pediatric clinical AVCO₂R trials for CO₂ retention syndromes and early ARDS.

Material and methods

All animals received humane care according to "Guide for the Care and Use of Laboratory Animals" (1985) prepared by the U.S. Department of Health and Human Services and published by the National Institutes of Health. The study was approved by the Institutional Animal Care and Use Committee of the University of Texas Medical Branch, Galveston, Tex., and performed with strict adherence to Committee guidelines regarding humane use of animals.

Adult Suffolk ewes ($n = 6$, 33 ± 5 kg) were used to investigate the effect of prolonged (7 days) AVCO₂R in a smoke inhalation injury model of severe respiratory failure. Femoral and pulmonary arterial lines were placed in the animals three days before the experiment. Baseline hemodynamic variables including heart rate, cardiac output, mean arterial pressure, pulmonary artery pressure, central venous pressure, and pulmonary artery wedge pressure were measured immediately before injury. After endotracheal intubation, anesthesia was maintained with inhaled halothane delivered through a volume-controlled ventilator (Servo 900C, Siemens-Elema). Tracheostomy was performed followed by cotton severe smoke inhalation/insufflation to induce severe respiratory failure to a median lethal dose as previously described.¹⁸ Animals were then allowed to recover from anesthesia and the lungs mechanically ventilated. Initial postinjury ventilator settings were as follows: respiratory rate 25 to 30 breaths/min, tidal volume 15 ml/kg, fraction of inspired oxygen (Fio₂) 1.0, and positive end-expiratory pressure 5 cm H₂O. Fio₂ was reduced once the carboxyhemoglobin level was less than 10% and maintained at a level sufficient to provide an arterial oxygen tension (PaO₂) level greater than 60 mm Hg. Hemodynamic variables and ventilator settings including minute ventilation and peak inspiratory pressure (PIP) were recorded. Arterial and mixed venous blood gas values were also measured every 6 hours, with minute ventilation and Fio₂ adjusted to maintain arterial pH at 7.35 to 7.45, PaO₂ at 60 to 150 mm Hg, and arterial carbon dioxide tension (Paco₂) at 30 to 40 mm Hg.

After 24 hours of volume-controlled ventilation, the sheep were reanesthetized and underwent systemic anticoagulation (300 IU/kg bovine lung heparin, Upjohn, Kalamazoo, Mich.) and cannulation of the left carotid artery (18F TF018LH, Research Medical, Midvale, Utah) and the left jugular vein (22F TF022L, Research Medical). A membrane gas exchanger (Affinity, Avecor Cardiovascular, Plymouth, Minn.) was primed with normal saline solution (270 ml) and connected to the vascular cannulas after de-airing. Animals were then allowed to recover from anesthesia and have free access to food and water. Activated clotting time (Hemochron 400, Interna-

Fig. 1. CO₂ removal during 7 days of AVCO₂R in an ovine model of severe smoke inhalation injury peaks at day 5 and begins a slow downward trend as the animal recovers and resumes more efficient gas exchange via the native lungs. Values of PaCO₂ (scaled on the *right ordinate*) remained within the normal range throughout the study. Values given as mean plus or minus the standard deviation. *Baseline*, Day 0, before injury; *injury*, day 0, before AVCO₂R.

tional Technidyne, Edison, N.J.) was maintained between 300 and 500 sec with a continuous heparin infusion throughout the study. The animals were then allowed to recover and continued to receive ventilator support before initiation of AVCO₂R.

On the initiation of AVCO₂R flow with extracorporeal CO₂ removal, ventilator support was reduced in a stepwise fashion as previously described.¹⁷ Initial reductions were made in tidal volume to reduce the PIP to less than 30 cm H₂O. Once targeted airway pressures were achieved, the respiratory rate was incrementally reduced to allow greater spontaneous respirations. Concurrently, the FiO₂ was reduced as the Pao₂ value remained above a threshold of 60 mm Hg. Positive end-expiratory pressure ranged from 5 to 10 cm H₂O. With full AVCO₂R flow, ventilator reductions continued daily throughout the study period until repeated blood gas sampling demonstrated Pao₂ values greater than 60 mm Hg with an Fio₂ of 0.21 and systemic PaCO₂ values remained less than 40 mm Hg, at which point mechanical ventilation was discontinued. Daily measurements of heart rate, cardiac output, mean arterial pressure, pulmonary artery pressure, blood flow, PIP, and CO₂ removal were recorded and systemic and pulmonary vascular resistance values were calculated and compared with baseline measurements.

AVCO₂R blood flow was monitored by an ultrasonic flow probe (model H6X, Transonic Systems, Ithaca, N.Y.) placed on the arterial cannula and interfaced with a real-time flowmeter (model HT 109, Transonic Systems) with a digital display. The arteriovenous pressure gradient

across the gas exchanger was calculated on the basis of the difference between the inlet and outlet pressures. Sweep gas flow (100% oxygen) was controlled by an in-line regulator. CO₂ removal by the device was calculated as the product of sweep gas flow and its exhaust CO₂ concentration measured by an in-line capnometer (Sara-Trans, Lenexa, Kans.). The animals received 24-hour bedside care and continued to receive mechanical ventilation for 7 days or until successfully weaned from ventilator support.

Data are expressed as mean plus or minus the standard error of the mean and were displayed and analyzed by the SigmaPlot and SigmaStat programs (Jandel Scientific, San Rafael, Calif.). Comparisons with baseline values (before injury) were made by one-way analysis of variance with Dunnett's test, with time treated as repeated measures.

Results

All animals survived the study period with five (83%) of six weaned from the ventilator before day 7. AVCO₂R allowed a reduction in ventilator pressure settings to maintain PIP at less than 30 cm H₂O throughout the study. CO₂ removal via AVCO₂R ranged from 99.7 ± 13.7 to 152.2 ± 16.2 ml/min over the course of the 7 days, while maintaining normocapnia (PaCO₂ ≤ 40 mm Hg) (Fig. 1). Peak CO₂ removal occurred at day 5 corresponding to the

Fig. 2. AVCO₂R blood flow and cardiac output remained stable and AVCO₂R flow ranged from 20.1% $\pm$ 1.4% to 25.9% $\pm$ 2.4% cardiac output for 7 days. Values given as mean plus or minus the standard deviation. Baseline, Day 0, before injury; injury, day 0, before AVCO₂R.

anticipated full manifestation of the severe smoke inhalation injury. After day 5, as the animals' lungs recovered and native lung ventilation increased, AVCO₂R blood flow was decreased in a stepwise fashion and extracorporeal CO₂ removal subsequently decreased. The values for extracorporeal flow rate, cardiac output, and flow as a percentage of cardiac output can be seen in Fig. 2. AVCO₂R flow throughout the 7-day study period ranged from 1.24 $\pm$ 0.06 to 1.43 $\pm$ 0.08 L/min, accounting for 20.1% $\pm$ 1.4% to 25.9% $\pm$ 2.4% of the cardiac output. Heart rate, mean arterial pressure, and pulmonary artery pressure values remained relatively constant and were not statistically different as compared with baseline values at any time during the study (Fig. 3). Likewise there were no significant changes in systemic or pulmonary vascular resis-

tance associated with AVCO₂R (Fig. 4). The pressure gradient across the oxygenator was less than 10 mm Hg, and there were no changes in the inlet and outlet pressures throughout the 7-day study. No clots were observed in the AVCO₂R circuit at necropsy. There were no observed incidences of acute or episodic hemodynamic instability or hemorrhagic or thromboembolic events throughout the 7-day study. Despite the severity of the injury and significant reduction in ventilatory support, Pao₂ was maintained at greater than 75 mm Hg with an Fio₂ of less than 0.5 at all times.

Discussion

Our recent work has shown that AVCO₂R is a simple technique to achieve total CO₂ removal in a large animal model of ARDS in which flow up to

Fig. 3. Heart rate (HR), mean arterial pressure (MAP), and pulmonary artery pressure (PAP) during the 7-day period of AVCO₂R revealed no statistically significant differences at any time. Values given as mean plus or minus the standard deviation. *Baseline*, Day 0, before injury; *injury*, day 0, before AVCO₂R.

29% cardiac output achieved total CO₂ removal and significantly reduced minute ventilation and peak airway pressures.¹⁷ In our initial studies of the performance characteristics of AVCO₂R, we determined that the quantity of CO₂ removed is directly dependent on blood flow through the gas exchanger.¹⁶ In healthy sheep, AVCO₂R flow of 0.5 L/min removes a sufficient quantity of CO₂ to maintain normocapnia, and mild permissive hypercapnia (Paco₂ of 60 to 70 mm Hg) results when AVCO₂R flow is reduced to only 0.2 L/min.¹⁹ Sufficient flow to achieve total CO₂ removal with AVCO₂R allows a significant reduction in ventilator airway pressure requirements and attendant barotrauma/volutrauma to the native lung alveoli. Before pediatric and adult clinical application of AVCO₂R for CO₂ retention syndromes or early ARDS, prolonged use of AVCO₂R must be demonstrated to be tolerated

hemodynamically without significant changes in heart rate, cardiac output, mean arterial pressure, pulmonary artery pressure, blood flow, PIP, or CO₂ removal. Therefore this study in a large animal model of ARDS was necessary to provide a risk/benefit assessment for the initial phase I clinical trials.

Patients with ARDS are often in a hemodynamically unstable condition with a tendency toward either a hypodynamic²⁰ or a hyperdynamic²¹ state depending on the cause and progression of ARDS. Volume- or pressure-controlled mechanical ventilation inflicts positive intrapleural pressure and may exacerbate such instability by directly affecting venous return and pulmonary vascular resistance. Modified ventilator management strategies, such as varying levels of positive end-expiratory pressure²² and manipulation of the inspiration/expiratory ratio,²³ have also been shown to change hemodynam-

Fig. 4. Systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR) calculated from directly measured variables during the 7-day period of AVCO₂R revealed no statistically significant difference at any time. Values given as mean plus or minus the standard deviation. *Baseline*, Day 0, before injury; *injury*, day 0, before AVCO₂R.

ics or organ blood flow during ARDS in both animal models and human beings. Permissive hypercapnia leads to increases in cardiac output, organ blood flow, and intracerebral pressure,²⁴ but these effects can be attenuated by the administration of sodium bicarbonate to offset the respiratory acidosis. The overall disease process and the resultant treatment are potentially additive in their impact on hemodynamic stability. The application of an additional treatment modality, that is, AVCO₂R, which uses up to 20% to 30% of the cardiac output to alleviate the need for excessive ventilator therapy to remove CO₂, could result in cardiac decompensation and worsening of the condition. On the other hand, by allowing CO₂ removal to occur without the need for continued ventilation with potentially harmful levels of volume and pressure, AVCO₂R allows a reduction in the applied airway pressures and resultant intrathoracic pressures and minimizes the hemodynamic insult caused by impairment of venous return

and cardiac output. These factors are paramount when considering AVCO₂R for use and must be fully understood before a treatment is initiated that may predispose an already critically ill patient to further hemodynamic compromise.

Early investigations into the physiologic response to an arteriovenous shunt in normal dogs showed that shunt flows ranging from 17% to 130% of the baseline cardiac output revealed either no change or a decrease of 10 to 30 mm Hg in mean arterial pressure.²⁵ Frank and coworkers²⁶ showed that a reflex vasoconstrictor response prevented a fall in mean arterial pressure and that physiologic accommodation occurred up to a shunt equal to or greater than 60% of the baseline cardiac output. These studies relied on extensive instrumentation in anesthetized, healthy animals and may not accurately reflect the true adaptive response. A long-term (2-month) rat model of an aortocaval fistula, totaling 50% of the cardiac output, demonstrated that

physiologic adaptation resulted in high-output cardiac failure with ventricular hypertrophy and regional blood flow redistribution.²⁷ This study illustrated the adaptation to an unusually large shunt in the rat, but a more clinically relevant short-term study with significantly lower shunt flows is necessary for AVCO₂R.

Several examples of arteriovenous shunts used for specific patient care circumstances or large animal studies exist. Gentilello and colleagues²⁸⁻³⁰ applied a simple percutaneous arteriovenous shunt connected to a countercurrent heat exchanger to speed rewarming in animals and patients with clinically significant hypothermia and reported a spontaneous arteriovenous shunt flow rate of 225 to 375 ml/min did not significantly alter hemodynamics. This method was significantly more efficient than simple external rewarming and was tolerated without adverse events or the need for anticoagulation. Awad and colleagues¹⁴ showed that AVCO₂R support for up to 7 days could be tolerated without adverse hemodynamic sequelae in healthy dogs and sheep. More recently studies in a canine model of acute oleic acid injury with an oxygenator in a pumpless arteriovenous shunt with flow rates sufficient to achieve adequate gas exchange (25% of baseline cardiac output) resulted in decreases in mean arterial pressure and systemic vascular resistance that could be attenuated with a dopamine infusion.¹⁵ These studies were done in an anesthetized animal with an oleic acid model known to be associated with hemodynamic compromise.^{31, 32}

Our data confirmed that despite a 20% to 26% cardiac shunt through the AVCO₂R circuit for 7 days, there was no instability in the hemodynamic profile, specifically in heart rate, cardiac output, mean arterial pressure, pulmonary artery pressure, or AVCO₂R flow. These data suggest that, in addition to its use in healthy animals,^{14, 33} long-term, high-flow AVCO₂R can be tolerated by adult sheep with severe respiratory failure without sequelae. The extremely low circuit resistance (<10 mm Hg) allows the AVCO₂R circuit to appear as an insignificant component of the overall systemic resistance without hemodynamic compromise on initiation of AVCO₂R flow. Redistribution of blood flow, with decreased blood flow to muscles and skin and sustained blood flow to the brain and heart, has been observed in the high-shunt, high-output cardiac failure model in conscious rats.²⁷ Some elements of this adaptive physiologic state may have been present during our 7-day study. In addition,

increased intrathoracic pressure as a result of positive-pressure ventilation will reduce venous return and subsequently cardiac output and systemic arterial blood pressure. By achieving a significant reduction in ventilatory pressures and eliminating hypercapnia, AVCO₂R may have attenuated changes in hemodynamics that would have otherwise been manifested during the study as a result of increased intrathoracic pressure from mechanical ventilation.

In our study, oxygenation was maintained with an Fio₂ ranging from 0.21 to 0.50, which was sufficient to maintain systemic Pao₂ values at greater than 75 mm Hg throughout the 7 days. AVCO₂R is not useful to provide supplemental O₂ delivery when the arterial Pao₂ level is adequate because the inflow to the gas exchanger is already well saturated, with O₂ carrying capacity at a maximum. To illustrate, hemoglobin is assumed to be 10 gm/dl, inlet O₂ saturation is 90% (corresponding to a Pao₂ value of 60 mm Hg), outlet O₂ saturation is 100%, and AVCO₂R flow is 1.4 L/min. The AVCO₂R O₂ exchange capacity under these conditions is at a theoretic maximum of approximately 19 ml/min. Estimating O₂ consumption at 150 to 250 ml/min per square meter, AVCO₂R contributes little to the overall oxygenation in a patient, especially in a patient who is in a hypermetabolic condition with an increased O₂ demand related to the disease state. If the alveoli are maintained open with the application of positive end-expiratory pressure, the passive diffusion of constant-flow O₂ across the alveolar membrane is adequate for systemic oxygenation as demonstrated by the technique of apneic oxygenation first popularized by Kolobow.¹⁰ There is also a small benefit related to the increased O₂ content of the mixed venous blood reaching the pulmonary precapillary bed, which results in a slight alteration in the normal vasoconstrictive response to local hypoxia with a resultant reduction in pulmonary shunt.

In conclusion, AVCO₂R can be used for total CO₂ removal for up to 7 days in an adult sheep model of severe respiratory failure without hemodynamic compromise or instability. The blood flow rates necessary to achieve total CO₂ removal by AVCO₂R to provide lung rest may allow vascular access with percutaneous cannulas. Our goal is to provide a simple bedside management tool to augment gas exchange in cases of developing ARDS to allow decreased barotrauma/volutrauma at an early stage when favorable outcomes are likely. In addition, the relative hemodynamic stability of this animal model of ARDS during prolonged AVCO₂R

validates the safety of this technique for clinical trials to evaluate AVCO₂R in syndromes of CO₂ retention and early respiratory failure in the adult and, subsequently, pediatric populations.
