PREDICTING LONG-TERM FUNCTIONAL RESULTS AFTER MYOCARDIAL REVASCULARIZATION IN ISCHEMIC CARDIOMYOPATHY

Giovanni Battista Luciani, MD
Giuseppe Montalbano, MD
Gianluca Casali, MD
Alessandro Mazzucco, MD

Objective: The goal of the present study was to define the early and late functional results after revascularization in ischemic cardiomyopathy and to identify variables predictive of a favorable outcome.

Methods: A retrospective review of all consecutive patients with ischemic cardiomyopathy undergoing myocardial revascularization between January 1991 and June 1998 was undertaken. One hundred sixty-seven patients (140 men) aged 60 ± 8 years (range, 39-77 years) with angina (n = 107), congestive heart failure (n = 54), or silent ischemia (n = 6) were identified. One hundred six (63%) patients with angina were in Canadian Cardiovascular Society class III or IV, and 40 (24%) patients with congestive failure were in New York Heart Association class III or IV. The preoperative left ventricular ejection fraction averaged 0.28 ± 0.05 (range, 0.16-0.30). Thirteen (8%) patients required preoperative mechanical life support. A mean of 2.9 ± 0.9 grafts per patient were performed, with an average myocardial ischemia time of 53 ± 23 minutes and bypass time of 104 ± 31 minutes.

Results: There were 3 (1.7%) early deaths and 21 (13%) deaths during follow-up (2.7 ± 2.1 years; range, 0.3-7.8 years), producing a survival of 94% ± 2% and 75% ± 10% at 1 and 5 years, respectively. Despite a significant increase in left ventricular ejection fraction (0.28 ± 0.05 vs 0.38 ± 0.09, P = .0001), only 89 (54%) patients were symptom-free at follow-up. Freedom from recurrent angina was 98% ± 1% and 81% ± 8%, whereas freedom from congestive failure was 78% ± 11% and 47% ± 20% at 1 and 5 years, respectively. Follow-up New York Heart Association class in patients with congestive failure was improved (40/54 class III-IV vs 11/54 class III-IV, P = .0001). Multivariate analysis showed a lower ejection fraction (P = .01), preoperative congestive failure (P = .03), and a need for preoperative intra-aortic balloon pumping (P = .03) to be associated with a greater prevalence of recurrent congestive failure, whereas male sex (P = .01), preoperative angina (P = .04), use of the internal thoracic artery (P = .03), and higher number of grafts (P = .01) were associated with lower prevalence. Male sex (P = .06), higher number of grafts (P = .04), and shorter duration of myocardial ischemia (P = .04) were also predictive of improvement in New York Heart Association class at follow-up.

Conclusions: Despite satisfactory early and late survival, late functional outcome after myocardial revascularization in ischemic cardiomyopathy remains suboptimal because of recurrence or persistence of congestive failure. Selection of appropriate surgical candidates and extensive use of complete revascularization with the internal thoracic artery may substantially improve functional results. (J Thorac Cardiovasc Surg 2000;120:478-89)
The rapid extension of heart transplantation to a wider category of patients with end-stage heart disease in the late 1980s has been responsible for the increasing discrepancy between the demand for heart transplantation and offers of viable donor organs. The realization that high-risk surgical options could be offered to selected patients initially evaluated as potential transplant recipients led several pilot institutions to redefine the relative indications for heart transplantation. It was readily apparent that a proportion of patients with end-stage ischemic heart disease could be offered myocardial revascularization at the expense of greater operative risk but with an overall early outcome absolutely comparable with that of heart transplantation. The awareness that selection criteria were needed to identify patients who would benefit from revascularization promoted the widespread use of laboratory investigation to identify areas of viable myocardium, albeit in a quiescent or hibernated state. Progress in the field of imaging and metabolic diagnostic techniques, as well as advancements in the strategies of intraoperative myocardial protection and postoperative care, must be credited for the significant decrease in operative risk for patients with ischemic cardiomyopathy undergoing coronary artery bypass surgery observed in the early 1990s. Medical management of congestive heart failure likewise witnessed substantial improvements with the introduction of angiotensin-converting enzyme inhibitors in clinical practice.

With the availability of a series of valid medical and surgical therapeutic options for ischemic cardiomyopathy, it has become necessary to identify more stringent selection criteria for revascularization. In particular, negligible attention has thus far been devoted to the assessment of late functional outcome of patients after coronary bypass surgery, which must also be taken into consideration when a treatment option is chosen. The purpose of the present study was to define the long-term functional results after myocardial revascularization for ischemic cardiomyopathy and to identify factors predictive of favorable outcome.

Methods

Patient selection. Between January 1991 and June 1998, 5579 consecutive patients with ischemic heart disease underwent myocardial revascularization (coronary artery bypass grafting) at our institution. One hundred sixty-seven (2.9%) had severe left ventricular failure (left ventricular ejection fraction [LVEF] < 30%) and were thus retrospectively selected for the study. Inclusion criteria throughout the observation period were clinical (ie, angina) evidence, laboratory (ie, positive stress test result) evidence, or both, of ischemic heart disease with angiographic demonstration of critical obstructive coronary artery lesions. Estimates of LVEF were gathered from biplanar left ventricular angiograms in all patients. Exclusion criteria were the presence of a recent (ie, <1 month old) myocardial infarction, the existence of valve disease, or the existence of a left ventricular aneurysm necessitating surgical treatment. Myocardial viability studies to further identify suitable surgical candidates were gradually adopted during the observation period and became routine at our institution only in 1994. Accordingly, stress and rest-redistribution 201 thallium scintiscan, low-dose dobutamine echocardiography, or both, were used to image areas of viable (ie, hibernated) myocardium. Because of cost considerations, positron emission tomography was used only in cases of inconclusive response with the aforementioned laboratory investigations or when both results were negative despite the presence of angina, as reported in the management algorithm depicted in Fig 1. The demographic variables of the patient population are summarized in Table I.

Operative technique. All procedures were performed through a median sternotomy with the aid of moderately hypothermic (28°C) cardiopulmonary bypass by using aortic and right atrial cannulation and left ventricular venting through the right superior pulmonary vein. Complete myocardial revascularization with venous and arterial conduits was the goal in every patient. Use of the left internal thoracic artery on the left anterior descending branch was routinely extended to all patients 70 years old or younger. In older patients the left internal thoracic artery was used on an individual basis. All distal coronary anastomoses were performed first. The proximal anastomoses were performed with total aortic crossclamping or partial occlusion at the surgeon’s discretion. Before 1995, myocardial preservation was obtained by intermittent injection of cold (4°C) crystalloid cardioplegic solution through the antegrade route. After aortic crossclamping, 1000 mL of St Thomas’ Hospital II solution was injected into the aortic root at a rate of 150 to 300 mL/min. The dose was continued in case of persistent electrical activity to achieve cardiac standstill. Topical cooling of the heart with ice-slush was also used. Maintenance doses (500 mL) of cardioplegic solution were administered every 30 minutes. After 1995, cold blood induction and maintenance and warm reperfusion cardioplegia through the antegrade and retrograde (ie, coronary sinus) routes was used according to Buckberg’s principles. A cold (4°C) induction dose of 10 mL/kg was administered at 150 to 300 mL/kg through the antegrade (two thirds of dose) and retrograde (one third of dose) routes. The dose was continued until cardiac standstill in case of persistent electrical activity. Maintenance cold doses of 5 mL/kg were administered through the coronary sinus every 20 minutes. Warm (30°C–32°C) reperfusion was administered alternatively through the antegrade or retrograde route at 150 to 300 mL/min for 3 minutes before aortic clamp release. The operative variables of the patient population are reported in Table II.

Follow-up. Perioperative information was obtained from hospital records. Cross-sectional follow-up was conducted between August and September 1998 by telephone interview...
or direct assessment at follow-up physical and laboratory examination. Patient follow-up was 100% complete.

Statistical analysis. Data were reported as mean values ± SD or as proportions. Comparison of continuous variables was done by a 2-tailed Student t test for paired data. The Pearson $\chi^2$ or Fisher exact tests were used for categoric variables as appropriate. Survival curves were constructed by the Kaplan-Meier method. Differences in survival were determined by the log-rank test. Multivariate correlates of survival were identified by the Cox proportional hazard method. Multivariate correlates of hospital death, recurrent angina, recurrent congestive failure, and improvement of Canadian Cardiovascular Society (CCS) and New York Heart Association (NYHA) class at follow-up were determined by stepwise logistic regression analysis. The list of variables entered in the analysis is as follows: age, sex, angina, congestive heart failure, silent ischemia, ventricular arrhythmia, hypertension, hyperlipidemia, diabetes, prior myocardial infarction, CCS functional class, NYHA functional class, laboratory evidence of viable myocardium, LVEF, prior cardiac operation, preoperative intra-aortic balloon pumping (IABP), year of operation, urgent operation, number of grafts, use of the left internal thoracic artery, duration of myocardial ischemia, duration of cardiopulmonary bypass, and use of blood cardioplegia.

The primary end points of the study were as follows: early mortality (before hospital discharge or within 30 days of operation), late mortality, cardiac-related mortality (myocardial infarction, congestive heart failure, arrhythmia, or sudden death), recurrence of angina, recurrence of heart failure, and functional outcome. Functional outcome was evaluated by comparison of preoperative and 6-month follow-up echocardiographic measurements of LVEF, preoperative and follow-up clinical status according to the NYHA for congestive heart failure and CCS for angina, and evaluation of qual-
ity of life. The latter was assessed by means of a simplified self-administered questionnaire, which examined prevalence of active employment and severity of subjective physical limitation (graded as limited activity, partial limitation, or no limitation).

Results

Early clinical outcome. There were 3 (1.7%) early deaths, all of which were of a cardiac cause. One patient died on the second postoperative day as a result of low cardiac output after perioperative myocardial infarction, despite mechanical life support with a left ventricular assist device. The second casualty was in a patient undergoing the third myocardial revascularization procedure for unstable angina, who manifested irreversible low output syndrome refractory to IABP and high-dose catecholamine support. Perioperative myocardial infarction was ruled out on the basis of laboratory and electrocardiographic findings. The third early death occurred in a patient with silent ischemia and a history of ventricular tachyarrhythmia who had an unremarkable recovery in the intensive care unit but experienced ventricular fibrillation on the regular ward. Univariate analysis demonstrated that angina was associated with a decreased risk of hospital mortality ($P = .04$), whereas prolonged duration of cardiopulmonary bypass was associated with an increased risk of the same event ($P = .03$). When entered into the multivariate analysis, none of the variables examined proved predictive.

Major nonfatal postoperative complications were observed in 40 (24%) patients. Postoperative myocardial infarction was diagnosed in 9 (5%) patients, 8 of whom required catecholamine and IABP support. Fourteen (8%) additional patients showed reversible low cardiac output syndrome in the absence of laboratory and electrocardiographic evidence of perioperative myocardial infarction. Hemodynamic stabilization was achieved by means of IABP support in 3 of these patients, 2 of whom had required preoperative IABP support as well. Life-threatening ventricular arrhythm-

mias were recorded in 5 (3%) patients, 1 of whom needed resuscitation with open-chest cardiac massage and an IABP, subsequently. Emergency repeat coronary angiography in the latter patient demonstrated patency of all the bypass grafts. Four (2%) patients required prolonged mechanical ventilatory support for respiratory failure. Two (1%) patients had a postoperative cerebrovascular accident, and 1 had acute renal failure necessitating dialysis. Postoperative bleeding leading to re-exploration occurred in 3 (2%) patients.

**Late clinical outcome.** Twenty-one late casualties were recorded during a follow-up period ranging from 0.3 to 7.8 years (mean, 2.7 ± 2.1 years). Actuarial survival was 94% ± 2%, 75% ± 8%, and 75% ± 8% at 1, 5, and 7 years, respectively (Fig 2). Cause of late mortality was cardiac in 15 patients (progressive heart failure in 7, sudden death in 5, and myocardial infarction in 3), giving an actuarial freedom from cardiac death of 95% ± 1%, 84% ± 5%, and 84% ± 5% at 1, 5, and 7 years, respectively. Noncardiac cause of death included malignancy in 5 patients and stroke in 1 patient. Multivariate analysis showed the number of bypass grafts and ejection fraction to be inversely correlated with late mortality, whereas duration of cardiopulmonary bypass was directly correlated with it (Table III). The significance of the following findings increased when late cardiac mortality was used as an end point (Table IV).

Late complications, excluding those of cardiac origin that are reported below, were cerebrovascular accident in 2 patients and right leg amputation in a patient with severe peripheral vascular disease.

**Late functional outcome.** Laboratory evidence of successful functional outcome of myocardial revascularization was suggested by a significant improvement in ejection fraction at 6-month follow-up echocardiography (0.28 ± 0.05 vs. 0.38 ± 0.09, P = .001). However, no correlates predictive of increase in ejection fraction could be isolated, possibly because of the wide distribution of follow-up values.

Eighty-nine (54%) of 164 operative survivors were symptom-free at follow-up assessment. Actuarial symptom-free survival for the entire patient population was 75% ± 8%, 41% ± 16%, and 31% ± 18% at 1, 5, and 7 years, respectively (Fig 3).

Recurrence angina was diagnosed in 17 (10%) operative survivors, 7 of whom had associated congestive failure. Fourteen of these patients had presented with angina at operation, whereas 3 had been referred for angina combined with congestive heart failure (Fig 4). Four of 10 patients with angina alone at follow-up had elective repeat coronary angiography, which showed patency of all 3 bypass grafts in 1 patient, of 2 of 3 grafts in 1 patient, of 1 of 3 grafts in 1 patient, and

occlusion of all grafts in the last patient. Two of the 4 patients undergoing repeat invasive evaluation received a percutaneous transluminal coronary angioplasty during the procedure, whereas the remaining patients with recurrent angina or mixed symptoms were assigned to medical treatment and showed either clinical improvement or stabilization. Actuarial freedom from recurrent angina was $98\% \pm 1\%$, $81\% \pm 8\%$, and $63\% \pm 10\%$ at 1, 5, and 7 years, respectively (Fig 5). No correlates of recurrent angina could be disclosed.

Fig 4. Diagram depicting the evolution of the clinical picture of 167 patients with ischemic cardiomyopathy undergoing myocardial revascularization at the University of Verona between January 1991 and June 1998. Note that the total number of patients at follow-up is 164, corresponding to the operative survivors. CHF, Congestive heart failure.

Fig 5. Overall angina-free survival of 167 patients with ischemic cardiomyopathy undergoing myocardial revascularization at the University of Verona between January 1991 and June 1998. Dashed lines represent 70% confidence limits.
Congestive heart failure was observed in 65 (40%) operative survivors at follow-up, 7 of whom manifested recurrent angina, as specified above. Thus actuarial freedom from recurrent congestive failure was 78% ± 10%, 47% ± 20%, and 42% ± 22% at 1, 5, and 7 years, respectively (Fig 6). Although all patients with recurrent angina had the same as a presenting symptom, this did not apply to patients showing recurrent, persistent, or newly diagnosed heart failure. The variability of the evolution of clinical status as related to the type of symptom at follow-up is depicted in Fig 4. Three patients with rapidly progressing congestive failure and absence of viable myocardium at follow-up evaluation were listed for heart transplantation. The remaining were maintained on medical therapy alone. Several variables were identified as correlates of recurrent heart failure. In particular, lower LVEF, presentation with congestive failure, and need for preoperative IABP were associated with a greater likelihood, whereas male sex, preoperative angina, use of a left internal thoracic graft, and greater number of bypass grafts were associated with a lesser likelihood of congestive heart failure at follow-up (Table V). Average CCS functional class for the entire population improved from 2.8 ± 0.9 to 1.7 ± 0.5 at follow-up (P = .01), whereas improvement in average NYHA functional class was not evident (1.6 ± 0.9 vs 1.7 ± 0.8, not significant), possibly because of the high prevalence of congestive heart failure at follow-up evaluation. When only patients presenting with heart failure were examined, however, a significant improvement in NYHA class was disclosed, as attested to by the shift of patients toward lower functional classes (40/54 patients preoperatively vs 11/54 patients postoperatively in NYHA class III-IV, P = .001). Multivariate correlates of improvement in CCS functional class could not be identified. On the contrary, male sex, presentation with angina, and higher number of bypass grafts had a positive predictive effect of improvement in NYHA class, whereas longer duration of myocardial ischemia had a negative predictive effect (Table VI).

Multivariate analysis with Cox model. NYHA, New York Heart Association.
A simplified, self-administered quality-of-life questionnaire was administered to all 143 long-term survivors (median age at follow-up of 65 years; range, 46-79 years), and 123 (90%) of them responded. Twenty-two patients had returned to active employment, representing 18% of the overall population and 36% of the patients below retirement age. Thirty-seven (29%) patients felt physically limited in their daily activity, 21 (16%) felt only partially limited, and 70 (55%) felt no limitation at all.

Discussion

Survival. Myocardial revascularization has evolved into a safe treatment modality for selected patients with ischemic cardiomyopathy. The present work demonstrates that coronary artery bypass grafting can nowadays be offered to patients with ischemic left ventricular failure at a low operative risk (as low as 2%) and with a satisfactory long-term outlook.

Comparison of survival estimates after myocardial revascularization with previously published series presents some shortcomings. In particular, patient selection criteria are not uniform among the various clinical reports, as regards the upper-end limit of LVEF and the criteria are not uniform among the various clinical sentences,13 but not by Kaul and coworkers,10 possibly because their study was limited to patients with ejection fractions below 20%. The number of bypass grafts in the current series expresses the completeness of revascularization because two thirds of patients had 3-vessel disease. Thus, the finding of an inverse relation between the number of grafts and late mortality once again matches the results of Trachiotis and colleagues,13 who found complete myocardial revascularization to be inversely correlated with late death. Both studies extend to ischemic cardiomyopathy, the principle that ability to completely revascularize the myocardium is of great prognostic significance for survival, as shown for coronary operations in general.22

Understanding of the role of duration of cardiopulmonary bypass, an operative variable indicative of more complex or complicated procedures, in predicting late survival is less immediate. This factor may also express the severity and extension of ischemic heart disease, whereby longer circulatory assistance may be required to wean a failing heart from bypass.

Functional outcome. Although most of the research efforts have focused on the demonstration that early and late survival after myocardial revascularization is indeed satisfactory, few studies have concentrated on the functional outcome after operation. The demonstration of a short-term improvement in LVEF has generally been regarded as an index of successful functional routine treatment modality. However, an even more important role has been played by the constant evolution throughout the last decade of time of patient selection criteria by means of prospective laboratory investigation and of retrospective risk stratification.10,13,17,20,21

Accordingly, reviews of large clinical series, such as the current one, have been carried out to isolate preoperative or intraoperative variables, which may predict the outcome of revascularization. Analysis of previous work shows that a series of patient characteristics may be associated with increased operative risk, including advanced age, female sex, lower ejection fraction, comorbid conditions, urgency of operation, and reoperation.10,13,17,20 Unfortunately, identification of factors predictive of early mortality proved unrewarding in the present experience, likely because of the very low number of events. On the contrary, both late overall and late cardiac mortality were associated with lower ejection fraction, lower number of bypass grafts, and longer duration of cardiopulmonary bypass. The relation between preoperative ejection fraction and long-term survival is intuitive because it may describe the severity of ischemic left ventricular failure. A similar correlation was also disclosed by Trachiotis and associates,13 but not by Kaul and coworkers,10 possibly because their study was limited to patients with ejection fractions below 20%. The number of bypass grafts in the current series expresses the completeness of revascularization because two thirds of patients had 3-vessel disease. Thus, the finding of an inverse relation between the number of grafts and late mortality once again matches the results of Trachiotis and colleagues,13 who found complete myocardial revascularization to be inversely correlated with late death. Both studies extend to ischemic cardiomyopathy, the principle that ability to completely revascularize the myocardium is of great prognostic significance for survival, as shown for coronary operations in general.22

Understanding of the role of duration of cardiopulmonary bypass, an operative variable indicative of more complex or complicated procedures, in predicting late survival is less immediate. This factor may also express the severity and extension of ischemic heart disease, whereby longer circulatory assistance may be required to wean a failing heart from bypass.
result. Contrary to this assumption, more recent evidence has clearly shown that increase in left ventricular systolic performance is not necessarily accompanied by clinical improvement, as it can be measured by NYHA classification, exercise capacity, or quality-of-life scores. These findings are of great relevance because medical management of congestive heart failure has also witnessed significant progress in terms of both survival and control of symptoms. Thus, the choice of the optimal treatment modality in the individual patient with ischemic cardiomyopathy has nowadays become more difficult. Simply looking for a survival benefit may be insufficient to discriminate among therapeutic alternatives.

The present experience shows that recurrence of symptoms late after operation remains a definite problem, despite successful functional outcome, as traditionally evaluated by an increase in LVEF (from 28% to 38%). In general, a 5-year symptom-free survival of 41% can hardly be considered satisfactory. Closer scrutiny of late functional outcome reveals that revascularization in ischemic cardiomyopathy offers durable relief from angina because more than 80% of patients are likely to be free from angina 5 years after operation. These results favorably compare with the raw estimates quoted by Trachiotis and colleagues (40% prevalence of return of angina at 5.8 years’ mean follow-up) and by Kaul and colleagues (35% prevalence at 3.6 years), albeit at a shorter average period of observation (10% prevalence at 2.7 years in the current series). Although generally found in patients who had angina as a presenting symptom, no variable proved predictive of recurrence in the present experience, once again because of the low number of events recorded during follow-up. Thus, it remains purely speculative whether this discrepancy in outcome, as well as the ability to adequately control recurrent angina simply by augmentation of medical therapy and interventional procedures, may be related to the more extensive use (62% of patients vs 20%-35% in the previous series) of the left internal thoracic artery as the conduit of choice for the left anterior descending artery, as demonstrated in the common coronary surgery population. Arterial revascularization may also have the potential for saving these critically ill patients from reoperation, which carries a high risk.

As a corollary to the aforementioned observations, congestive heart failure is primarily responsible for the disappointing high prevalence of persistence or return of symptoms late after operation. This is evident by the extent of overlap between the two respective survival curves (Figs 3 and 6). Estimates of recurrent heart failure are uncommonly reported and vary widely among series of patients with ischemic cardiomyopathy, ranging from 28% to 63%. The present result (ie, 40%) is consistent with previous findings. Unlike angina, congestive heart failure may present in any patient subgroup, which is attested to by the fact that half of the symptomatic patients had originally presented with angina and were free from it at follow-up. It is conceivable that de novo appearance of heart failure expresses the relentless evolution toward left ventricular insufficiency, which would not be recognized by short-term echocardiographic assessment as it was carried out in this study and in the majority of previous studies. Longitudinal measurement of LVEF is warranted to disclose the relation, if any, between left ventricular systolic function and congestive heart failure late after operation.

Predicting the recurrence or appearance of heart failure has enormous bearing in terms of patient selection, given that late survival after bypass grafting and transplantation is similar, but the quality of life with the latter is affected by the need for long-term medication and the attendant risks of immunosuppression. In the present experience, female sex, history of congestive failure, lower ejection fraction, and need for preoperative IABP support were associated with greater likelihood of heart failure at follow-up. On the contrary, history of angina, use of the left internal thoracic artery, and number of bypass grafts were inversely associated with return of congestive failure. The meaning of clinical variables is rather apparent, even though a relation with recurrent heart failure has never been previously proposed. In fact, female sex has often been associated with adverse late outcome after revascularization in ischemic cardiomyopathy, as have history of congestive failure and lower ejection fraction. The need for preoperative IABP may further identify patients with more severe left ventricular insufficiency. Comparison with existing data is troublesome because few investigators have analyzed return of heart failure in large clinical series. Yamaguchi and colleagues found diabetes and preoperative left ventricular end-systolic volume index (>100 mL/m²), but not history of congestive failure, to be predictive of recurrent heart failure in 39 operative survivors followed up for a mean of 3.6 years. The smaller number of patients and the higher proportion with preoperative heart failure (31/41 [76%] vs 54/167 [32%]) can account for the discrepancy with the present findings. Whereas the demographic characteristics isolated have an effect on patient selection, the operative variables identified herein have relevant therapeutic implications. Indeed, the unprecedented
ed finding that more extensive use of left internal thoracic artery grafts and of complete revascularization may reduce the prevalence of congestive failure late after operation corresponds well to similar conclusions reached by historical studies on the general coronary bypass population. Inability to show a correlation between the type of conduit for revascularization and late cardiac events or control of symptoms by past studies on ischemic cardiomyopathy may have been due to low prevalence of left internal thoracic artery use (ie, between 20% and 35% when reported). Common reasons for not using the internal thoracic artery in patients with left ventricular failure during the 1980s were advanced age, urgency of operation, and modest concern for long-term prognosis. The clinical experience of the past decade has decisively solved these reservations, as confirmed by the present work; therefore, no patient with ischemic cardiomyopathy should be denied a left internal thoracic artery graft. Consensus already exists on the importance of complete myocardial revascularization in decreasing the rate of late adverse events, although the specific role on recurrence of heart failure has not been established previously.

The substantial prevalence of congestive heart failure at follow-up explains the absence of improvement in mean NYHA functional class of the overall population. It is, however, noteworthy that patients with heart failure had significant attenuation of symptoms, and half of them were asymptomatic at follow-up. This suggests that revascularization may be associated with durable functional improvement, even in patients with pure congestive failure, although less commonly than in patients with a history of angina, as shown by the relation between the latter variable and NYHA class at multivariate analysis. Similar to the results obtained with recurrence of heart failure, male sex and greater number of bypass grafts were predictive of amelioration in functional class. On the basis of the present results, complete myocardial revascularization has the potential for decreasing not only late mortality but also the prevalence and severity of congestive failure. It follows that coronary operations without the use of cardiopulmonary bypass, by definition associated with incomplete revascularization, are not ideally suited for patients with ischemic cardiomyopathy, as recently advocated.

Quality of life was satisfactory in most long-term survivors of coronary bypass grafting, albeit assessed by a rather rudimentary questionnaire limited to mobility status and active employment. Given the profile of the patient population (large number, advanced age, and variable social background), it was believed that compliance to a simplified test would be the greatest. Although no attempt was made at correlating quality of life with preoperative parameters, previous studies with either the Minnesota Living with Heart Failure or the Nottingham Health Profile have failed to disclose any relation with clinical or laboratory data. In particular, it has been shown that identification of viable myocardium (≥8 segments at positron emission tomography) may predict improvement in LVEF or exercise capacity but not changes in functional class or quality of life.

Finally, considering half of the population of long-term survivors in the present experience was above retirement age at the time of follow-up, an overall active employment rate of 18% is not necessarily disappointing. In addition, over 70% of patients felt no or modest physical limitation in routine physical activity, which indicates acceptable functional status despite the high prevalence of persistent or newly presenting heart failure.

**Limitations.** The current study presents several limitations. It is retrospective and, like most clinical series of surgical revascularization in ischemic cardiomyopathy, not randomized. The bias introduced by changing clinical practice (ie, increasing adoption of blood cardioplegia, myocardial viability tests, and use of the left internal thoracic artery) cannot be easily quantified. Late follow-up echocardiographic and, most important, coronary angiographic examinations were not performed. It is difficult to understand whether unsatisfactory functional outcome is a result of progressing left ventricular insufficiency in turn because of the natural history of bypass grafts or alternatively because of a relentless evolution of the myopathy. This shortcoming afflicts all previously published clinical series. Use of NYHA and CCS classification to measure clinical and functional status has inherent limitations. Different methods, such as the Specific Activity Scale, have instead been proposed, which have greater agreement with exercise treadmill performance. Nonetheless, NYHA and CCS remain the most commonly adopted scoring systems, and continued use is warranted if clinical series are to be compared.

**Conclusions**

The present study demonstrates that operative and late survival after myocardial revascularization in ischemic cardiomyopathy is satisfactory. Whereas durable relief from angina can be expected in the majority of long-term survivors, persistence of congestive heart failure, albeit of lesser severity, or its new appearance represent concerning problems in the late
follow-up. Patients who present with pure congestive heart failure and lower ejection fractions are at higher risk for late death and return of congestive failure. However, they should not be denied revascularization solely on this basis because evidence for clinical improvement exists. Regardless of the clinical substrate, extension to all patients of complete myocardial revascularization and use of the left internal thoracic artery graft is strongly recommended because it may reduce the mortality and the prevalence and severity of recurrent congestive failure late after the operation.
