artery (ITA) together with one or more saphenous vein grafts (SVGs). The major surgical objective is to supply the left anterior descending (LAD) coronary artery with an ITA to improve the patient’s survival. Since SVG failure is a major drawback of CABG, surgical techniques that involve minimal use of SVGs were attempted. In most centers, the ITA is isolated from the chest wall as a pedicle, together with the vein, muscle, fat, and accompanying endothoracic fascia. Harvesting is relatively quick because cautery is used to separate the pedicle from the chest wall. However, cautery damages the blood supply to the sternum which, in turn, impedes sternal healing and exposes the sternum to the risks of early dehiscence and infection in operations involving both ITAs. The risk of sternal infection is particularly high in patients with preoperatively limited sternal blood supply, such as those who are elderly and those who have diabetes.

As life expectancy increases, more elderly patients are being referred for coronary artery bypass grafting (CABG). The current conventional and most commonly used operative procedure for myocardial revascularization in patients of all ages involves one internal thoracic artery (ITA) together with one or more saphenous vein grafts (SVGs). The major surgical objective is to supply the left anterior descending (LAD) coronary artery with an ITA to improve the patient’s survival.

Since SVG failure is a major drawback of CABG, surgical techniques that involve minimal use of SVGs were attempted. In most centers, the ITA is isolated from the chest wall as a pedicle, together with the vein, muscle, fat, and accompanying endothoracic fascia. Harvesting is relatively quick because cautery is used to separate the pedicle from the chest wall. However, cautery damages the blood supply to the sternum which, in turn, impedes sternal healing and exposes the sternum to the risks of early dehiscence and infection in operations involving both ITAs. The risk of sternal infection is particularly high in patients with preoperatively limited sternal blood supply, such as those who are elderly and those who have diabetes.
A surgical technique was recently developed wherein the ITA is dissected as a skeletonized vessel. The skeletonized artery is isolated gently with scissors and silver clips, without the use of cauterization. Skeletonized ITA dissection leaves the vein, muscle, and accompanying tissue in place. The advantages are that the dissected ITA is longer and that its spontaneous blood flow is greater than that of the pedicled ITA, allowing the use of both ITAs as grafts to all necessary coronary vessels. No additional vein grafts are required in most cases. Another advantage of using the ITA as a skeletonized artery is the preservation of collateral blood supply to the sternum, enabling more rapid healing and decreasing the risk of infection.

The bilateral skeletonized ITA technique was adopted in our service as the preferred method for myocardial revascularization. The routine use of SVGs was stopped in April 1996, and they are currently used as a third optional graft (the second is the right gastroepiploic artery) or in emergency CABG operations.

Between May 1996 and May 1998, 781 consecutive patients underwent CABG with bilateral skeletonized ITAs. In this report, we analyze the early and midterm results of a subgroup of elderly patients in whom this surgical technique was used.

**Patients and methods**

Between May 1996 and May 1998, 303 consecutive patients 70 years or older underwent CABG by means of the bilateral skeletonized ITA technique. They comprised 38% of the 781 patients who underwent CABG surgery with bilateral skeletonized ITAs during this period in the Tel Aviv Sourasky Medical Center.

The patients’ preoperative and operative characteristics are listed in Table I. The ITAs were dissected as skeletonized arteries before heparin administration to decrease the risk of damage and hematoma formation in the region of the side branches during dissection.

Injury to the ITAs was extremely uncommon, happening mainly during the learning curve period. The reasons for this low occurrence of injury are as follows:

1. The work is delicate and refined and takes longer to perform than the standard technique
2. Cautery, which might cause direct or indirect injury, is not used
3. The technique of skeletonized ITA dissection is performed routinely and daily in our operating rooms

Operations were performed with cardiopulmonary bypass. The myocardial preservation technique involved intermittent warm cardioplegia (30°C-32°C). Our strategies for complete arterial revascularization are detailed in a recently published study by Gurevitch and associates.
We prefer to use bilateral ITAs as in situ grafts for myocardial revascularization. The 2 ITAs in combination with the right gastroepiploic artery give us 3 sources of blood supply. We believe that more blood sources are associated with improved long-term outcome. The cross arrangement (Fig 1, A) is based on the assumption that patency rate of the right ITA on the LAD coronary artery is similar to that of the left ITA on the LAD. To improve late survival, one should make every effort to use both ITA grafts for the left system. In 60 patients (20%), the right gastroepiploic artery was used as a third arterial conduit to bypass the posterior descending branch of the right coronary artery (Fig 1, A).

We do not use the cross technique in patients with a short right ITA, very long ascending aorta, enlarged right ventricle, too distal or unpredictable LAD anastomotic site, or a high probability of future reoperations (eg, combined aortic valve replacement and CABG). In most of these patients (204 patients) we use the composite arterial grafting technique.

The composite graft can be prepared before connection to cardiopulmonary bypass. Most of the composite grafts included end-to-side anastomosis of the free right ITA on an in situ left ITA (Fig 2, A). To date, injury to the ITA necessitating a revision of the original operative plan has occurred in fewer than 5% of our patients; in most, except for a very few cases, the operation can still be based on both ITAs.

If injury is caused to the proximal right ITA, the operation can still be based on constructing a composite graft, wherein the free right ITA graft is anastomosed end to side to the in situ left ITA. The operative plan is changed in these cases only when our original plan was to use the “cross” technique.

If the proximal left ITA is injured, a reverse composite graft can be constructed, with the free left ITA being connected end to side to the in situ right ITA. This arrangement of a free left ITA on in situ right ITA can also be used when the spontaneous free flow of the left ITA is inadequate (Fig 2, B).

When no graft to the posterior wall of the heart (the circumflex region) was necessary (26 patients), the left ITA was grafted to the LAD and the right ITA to the right coronary artery or its posterior descending branch (Fig 1, B). In most cases, it is impossible to reach this branch with the right ITA graft when using the regular technique of isolating the pedicled ITA. The skeletonized right ITA, however, is longer and, therefore, can usually reach the better-quality distal posterior descending artery. Another variation of composite grafting was the small Y-graft, wherein a small distal section of an ITA was anastomosed end to side to a more proximal part of the same artery (Fig 1, B).

The small Y-graft was performed in 35 patients in all 3 groups. In most cases it was used for LAD diagonal grafting.
In 2 cases it was used for an intermediate branch, and in 1 the left ITA was anastomosed to the first marginal and the Y-graft to the intermediate branch.

Our current preference is to use the small Y-graft for the LAD diagonal branch when we do not need grafts to the circumflex system. In cases that require grafts to the circumflex system, the left ITA is anastomosed to the LAD, and the diagonal is one of the vessels supplied by the right ITA (sequential grafting).

To decrease the risk of spasm of the arterial grafts, we treated all patients with high-dose intravenous infusion of isosorbide dinitrate (Isoret, 4–20 mg/h) during the first 24 to 48 hours after the operation. Systolic blood pressure was maintained above 100 to 120 mm Hg. From the second postoperative day, the patients whose gastroepiploic artery was used were treated with calcium channel blockers (diltiazem, 90–180 mg/day orally) for at least 3 months.

**Statistical analysis.** Data are expressed as mean ± standard deviation or proportions. The Fisher exact test and 2-sample *t* tests were used to compare discrete and continuous variables, respectively. The multivariate Cox proportional hazard model was used to evaluate the influence of preoperative variables on overall mortality (early plus late).

The log-rank test was performed twice to examine the effect of the operation on short-term survival. The first test specifically compared 1-year survivals and the second test (a global test) compared 3-year survivals.

Postoperative survival was expressed by the Kaplan-Meier method and survival curves were compared by the log-rank test. All analyses were performed with SPSS 7.5 software (SPSS, Inc, Chicago, Ill).

**Results**

The 303 elderly patients in the study received from 2 to 6 grafts (mean 3.1) each. The average cardiopulmonary bypass time was 77.9 ± 36 minutes, and aortic crossclamping time was 62 ± 29 minutes. Operative mortality (30 days postoperatively) was 2.6% (8 patients) (Table 1). The mortality of the octogenarians was higher (6.8%) than that of the younger patients (1.9%) (*P* = .06). Postoperative morbidity included perioperative myocardial infarction in 7 (2.3%) patients and stroke in 8 (2.6%) patients (4 were left with permanent neurologic deficiency and 4 recovered completely). Six patients (2.0%) had a sternal wound infection, 1 of whom was included in the perioperative mortality data. Seven patients (2.3%) had postoperative bleeding that required reopening the chest.
The use of the left ITA as a bypass graft has been shown to result in better early patency and improved survival in all patients, including elderly ones, but most published series failed to show additional survival benefit with bilateral ITA grafting. The lack of survival benefits and the technical complexity in performing complete arterial revascularization with bilateral ITAs are the probable reasons for the relative lack of popularity of this technique. For example, the New York State Cardiac Surgery database for 1996 reported 19,659 isolated CABG cases, of which only 1554 (8%) involved bilateral ITA grafting. The Society of Thoracic Surgery (STS) database included 153,000 CABG operations, of which only 4% involved bilateral ITAs.

In contrast to most of the previously published reports, 3 important large-scale studies have shown that long-term survival with bilateral ITAs is better than that with a single ITA. Lytle and associates reported that the 10- and 15-year survivals of patients undergoing bilateral ITA grafting were 84% and 67% compared with 79% and 64%, respectively, for patients with single ITA grafts. Reoperative and angina-free survivals, as well as freedom from additional revascularization procedures, were significantly higher in the group of patients who received bilateral ITA grafts.
bilateral ITA subset. In another study performed by Buxton and associates, the 10-year actuarial survival of patients receiving bilateral ITA grafts was 86% ± 3%, compared with 71% ± 5% for those receiving a single ITA graft ($P < .001$). In that report, the use of bilateral ITAs improved the rate of freedom from late myocardial infarction and reoperations. In the third report, Schmidt and colleagues demonstrated that survival benefit with bilateral ITA operations is achieved by grafting the ITA conduits to coronary arteries supplying the left ventricle rather than the right coronary system.

The use of bilateral ITA grafts in elderly patients is controversial. He and coworkers reported an operative mortality of 24% in elderly patients (≥70 years) who underwent bilateral ITA grafting. Moreover, use of bilateral ITA grafts in the older patients in their report was found to be a major risk factor for operative mortality, since mortality in the patients receiving 1 ITA was only 6.8% ($P < .007$). The ITA in their report was used as a pedicled conduit and, as they stated, the fact that only 4% of the patients received bilateral ITA grafts might have explained the higher operative mortality and increased use of postoperative intra-aortic balloon pumping (16.2% vs 5.9%, $P < .02$).

In a study by Lytle and associates, the number of patients older than 60 years operated on with bilateral ITA grafts was relatively small; however, bilateral ITA grafting improved survival of this subset of older patients when compared with patients older than 60 years with a single ITA graft.

In all the above series, extensive arterial grafting with bilateral ITAs was used preferentially in a selected group of young male non-obese nondiabetic patients. The only large series (1467 patients) comparing bilateral with single ITA grafting in elderly patients was reported by Galbut and associates. In this study, patients with bilateral ITAs had a lower hospital mortality (3.1%) than patients with a single ITA (6.4%), and the late survival (mean 43 months) was better as well (69.7% vs 60.7%).

Most studies reporting results of bilateral ITA grafting contain small numbers of patients operated on over a relatively long period. Patients were preselected for this procedure according to their life expectancy, and few of the patients older than 70 years were offered the option of bilateral ITA grafting. Unlike those reports, our series and that of Galbut and coworkers describe results in a nonselected group of patients. Complete arterial grafting with bilateral ITAs was the preferred method of myocardial revascularization for all ages during the 24-month study period. Bilateral ITA grafting was performed in 71% of the patients referred for CABG during this period, and 38% of them were 70 years or older.

Mortality and morbidity of our patients 70 years or older (2.6%) compared favorably with mortality described in procedures in which one ITA was used. Although the mortality of octogenarians was higher (6.8%) than that of patients younger than 80 years (1.9%), the difference did not reach statistical significance.

In the report by Lytle and colleagues, the only morbidity event that differed between the bilateral and single ITA groups was the difference in sternal wound complication (2.5% and 1.4%, respectively). Harvesting the
ITA as a wide muscular fascial pedicle with the aid of electrocautery was shown to devascularize sternal collateral blood supply and expose the sternum to increased risk of poor healing, dehiscence, and infection. Our report conferred significant clinical support to the assumption that the skeletonized ITA technique causes less damage to the sternal blood flow and, therefore, our rates of sternal infections and complications with bilateral ITA grafting are in the lower ranges of those reported by others. Despite the fact that the sternum of elderly patients is sometimes more fragile because of osteoporosis and suboptimal blood supply, old age in this report was not found to be associated with an increased occurrence of sternal infections. The occurrence of sternal infection in patients older than 80 years was 2.3% (1 patient), compared with 1.9% (5 patients) in patients between 70 and 80 years. On the other hand, increased occurrence of sternal infection in this report was found in patients with chronic lung disease. Increased respiratory forces causing high suture line pressure can probably explain the increased occurrence of sternal complications in this subgroup of elderly patients.

Another interesting finding of our study is the increased occurrence of postoperative stroke in patients with diabetes, which was 4 times higher than that in patients who did not have diabetes (6% vs 1.4%). Diabetes mellitus and the use of SVGs were the only predictors of postoperative stroke identified in this cohort of 303 elderly patients with bilateral ITA grafting. However, in this series SVGs were used in only a small group of patients.

In a recently published multicenter prospective study on 2108 patients, Roach and coworkers reported an occurrence of 6.1% for adverse cerebral outcome and 3.1% for strokes (fatal and nonfatal) after CABG. The occurrence of strokes was 5 times as high in patients with intraoperative palpable atherosclerotic plaque in the proximal aorta. Despite the older age of the patients in our present report (mean age 75.5 years, with 44 of them ≥ 80 years), the occurrence of postoperative stroke was similar to that in the report by Roach’s group (2.6% vs 3.1%). This may be explained by the fact that complete arterial revascularization was achieved without the use of vein grafting in 90% of the patients.

Complete arterial revascularization without vein grafting limits aortic manipulations to aortic cannulation, crossclamping, and insertion of the cardioplegia needle. Atherosclerosis of the aorta and large vessels, including those of the brain, affects more older patients and is more severe and extensive in patients with diabetes than in those without diabetes. The diffuse and advanced nature of the atherosclerotic plaques in the aorta and brain vessels of the elderly patients with diabetes is probably the best explanation for the higher incidence of stroke in this subset of patients in our report. Another possible explanation is the elevated level of β-thromboglobulin and circulating platelet aggregates in their blood, which may reflect platelet activation and cause microemboli postoperatively. The midterm results of this study include up to 3 years of follow-up. The decreased survival after emergency operations probably results from the relatively high operative mortality. The increased operative mortality and sternal infections necessitating sternectomy and long-term hospitalization among patients with COPD were the main causes of decreased survival in this subset of patients. Age 80 years or older was also associated with decreased late survival; however, the difference in survival became significant only 2 years after the operation. This suggests that late mortality of octogenarians may be related to factors other than the operative procedure, such as the life expectancy of individuals of such advanced age.

In conclusion, the skeletonizing dissection technique enables safe performance of complete arterial revascularization with bilateral ITAs in patients 70 years or older. This new surgical technique is associated with a low rate of sternal infection because of preservation of sternal collateral blood supply. Morbidity associated with leg wound incisions—an integral part of saphenous vein harvesting—was circumvented. We therefore recommend the routine use of bilateral skeletonized ITA grafting for most patients 70 years or older. The technique should not be used in emergency operations or in patients with COPD who bear an increased risk of sternal infection.

We thank Esther Eshkol for editorial assistance.
