Endovascular stent-graft repair for thoracic aortic aneurysm associated with right-sided aortic arch

Kenji Okada, MD,a Taijiro Sueda, MD,a Kazumasa Orihashi, MD,a Masanobu Watari, MD,a and Akira Naito, MD,b Hiroshima, Japan

Right-sided aortic arch with both left descending aorta and a retroesophageal aortic segment is an uncommon congenital vascular malformation. This abnormal anatomy is awkward to treat surgically. Recently endovascular stent-graft repair, which is less invasive than conventional surgical procedures, was applied in thoracic aortic aneurysm and showed good early results. We report here a case of thoracic aortic aneurysm associated with right-sided aortic arch that was successfully managed with an endovascular stent-graft.

Clinical Summary
A 76-year-old man was admitted to our hospital with a diagnosis of atherosclerotic aneurysm of the thoracic aorta associated with right-sided aortic arch. The patient had undergone coronary artery bypass grafting 10 years earlier, in which the right internal thoracic artery and a saphenous vein graft were anastomosed to the left anterior descending artery. Transluminal endovascular grafting was indicated because the right femoral artery and deployed with the guidance of transesophageal echocardiography and fluoroscopy. Before deployment of the stent-graft, the mean arterial pressure was lowered to 70 mmHg with the aid of an occlusion balloon in the superior and the inferior caval veins to avoid graft migration. A second aortogram revealed a small endoleak immediately after the deployment. The postoperative course was uneventful. A small leakage from the stent-graft shown on CT 2 weeks after the intervention disappeared in the next 6 weeks (Figure 2).

Comment
Right-sided aortic arch is an uncommon congenital anomaly with an incidence of 0.1%. Thoracic aortic aneurysm associated with right-sided aortic arch is also a rare disorder, only 4 cases of surgical treatment of this disorder having been reported. Three anatomic findings of right-sided aortic arch make surgical treatment difficult: (1) the pattern of the aortic arch vessels, (2) the location of the descending aorta, and (3) the relation between the esophagus and the aortic arch. Caus and associates performed bilateral thoracotomy because the esophagus was located in front of the arch and the descending aortas were in different pleural spaces. In our patient, the right internal thoracic artery, which was anastomosed to the left anterior descending artery, was positioned over the heart. Thus, either secondary mediastinum or bilateral thoracotomy seemed to be complicated and difficult.

Endovascular stent-graft repair has become a viable therapeutic alternative in the treatment of patients with thoracic aortic aneurysm. This technique is less invasive than standard techniques and brings acceptable morbidity and mortality rates. The presence of a curve and branch vessels in the aortic arch makes it difficult to apply this method to aortic arch diseases. There are considered to be 3 major prerequisites for such repairs: sufficient size of the arteries providing access, limited tortuosity of the distal aortic arch, and proximal neck morphology. Specifically, suitability entails relatively straight portions of the aorta and the absence of important side branches.

In the present patient, the distal part of the aortic arch was relatively straight, the 3 cervical branches had arisen from the ascending aorta, and the left subclavian artery was totally occluded. These anatomic features made the landing zone between the right subclavian artery and the aneurysm long enough to develop a stent-graft.
These conditions were suitable for endovascular stent-graft repair in this patient. This is the first patient treated with an endovascular stent-graft for thoracic aortic aneurysm with a right-sided aortic arch. Endovascular stent-graft repair is an alternative in the treatment of this entity.
