Objective: The effects of microfibrillar collagen hemostat (Colgel) and oxidized cellulose (Surgicel) on bleeding and allogeneic transfusions were compared in cardiac operations with a predicted high risk of bleeding.

Methods: Between August 1999 and November 2001, 71 patients undergoing elective, high risk of bleeding operations were studied after giving informed consent. The procedures included repeat cardiac operations (aorta-coronary bypass operations or valvular operations), ascending aortic aneurysm repair necessitating deep hypothermic circulatory arrest, and ascending aortic grafting without deep hypothermic circulatory arrest. Subjects were excluded if they had recent (<5 days) acetylsalicylic acid ingestion, thrombolytic therapy, or anticoagulant therapy (heparin <4 hours preoperatively or warfarin <3 days preoperatively). Consenting subjects were randomized to receive either Colgel or Surgicel.

Results: Chest tube drainage in the first 24 hours was 373 ± 143 mL in the Colgel group and 571 ± 144 mL in the Surgicel group (P = .01). Total postoperative chest tube drainage was 423 ± 154 mL (range, 280-1100 mL) in the Colgel group and 677 ± 128 mL (range, 285-1350 mL) in the Surgicel group (P = .01). In addition, chest tube drainage was compared between the 2 groups every 3 hours after operation. Blood loss in the first 3 postoperative hours was significantly less in the Colgel group (132 ± 41 vs 228 ± 57 mL, P < .001). In the following 3-hour interval, this significant difference persisted (67 ± 24 vs 121 ± 49 mL, P < .001).

Conclusions: In conclusion, the easy application, low cost, and significant blood-loss reduction effect of microfibrillar collagen powder renders this agent attractive for cardiac operations associated with high risk of bleeding.

Cardiovascular surgery is associated with a significant consumption of allogeneic blood products, often as a result of acquired hemostatic defects and/or incomplete surgical hemostasis. Management of the abnormal bleeding exposes the patient to the morbidity of reoperation and/or excessive, and sometimes inappropriate, blood-product transfusions. However, some patients or operations are at an increased risk for allogeneic transfusions because of excessive bleeding perioperatively. The risk factors include repeat cardiac operation; complex procedures, such as multiple valve replacements or aortic arch repairs; and procedures requiring...
long cardiopulmonary bypass (CPB) times, such as combined procedures (valve replacement plus myocardial revascularization). For aortic operations necessitating deep hypothermic circulatory arrest (DHCA), hypothermia accounts for the dysfunction of the normal coagulation mechanisms.

Pharmacologic agents to reduce bleeding have gained much interest recently because they are readily available, easy to administer, can be used prophylactically, do not require the use of costly equipment, and appear to be very safe and efficacious. The perioperative use of tranexamic acid, epsilon-aminocaproic acid, and aprotinin have gained acceptance around the world for the prophylactic reduction of allogeneic blood transfusions in cardiac operation patients.

Various surgical tissue adhesives have been investigated to control bleeding from suture lines and needle holes in synthetic grafts to native aortic tissues. In the effort to control bleeding from suture lines and needle holes in synthetic grafts to native aortic tissues. In the effort to control bleeding from suture lines and needle holes in synthetic grafts to native aortic tissues.

In this comparative randomized trial, we compared the efficacy of microfibrillar collagen hemostat (Colgel) and Surgicel in cardiac operations with a predicted high risk of bleeding.

**Patients and Methods**

Between August 1999 and November 2001, 71 patients undergoing elective, high risk of bleeding operations were studied after giving informed consent. The procedures included repeat cardiac operations (aorta-coronary bypass [ACB] or valvular operations), ascending aortic aneurysm repair necessitating DHCA, and ascending aortic grafting without DHCA. Subjects were excluded if they had recent (<5 days) acetylsalicylic acid ingestion, thrombolytic therapy (streptokinase, urokinase, or tissue plasminogen activator <1 day), or anticoagulant therapy (heparin <4 hours preoperatively or warfarin <3 days preoperatively). Also, subjects with preexisting coagulation defects (including abnormal procoagulative and anticoagulative parameters) were noted when the anesthesia team was sprayed with fibrin glue prior to sternal closure. In this comparative randomized trial, we compared the efficacy of microfibrillar collagen hemostat (Colgel) and Surgicel in cardiac operations with a predicted high risk of bleeding.

At the intensive care unit, continuous low-grade suction (50 cm-H\textsubscript{2}O) was applied. Complete blood count, PT, partial thromboplastin time, and platelet counts were measured before the operation and when the patients arrived at the intensive care unit. The drainage of mediastinal blood was measured hourly. The mediastinal and thoracic drains were removed when the total drainage was less than 150 mL over the previous 24 hours. Uniform transfusion criteria were adhered to in all patients. Blood and blood components were administered when the hematocrit level fell to less than 0.24 or the hemoglobin level fell to 7.5 g/L in the postoperative period. Shed mediastinal blood was not transfused into any patient during this study. The indication for perioperative random donor platelets, fresh frozen plasma, was the presence of excessive active bleeding (>200 mL/h), and a laboratory-demonstrated coagulation defect (platelet count <100×10\textsuperscript{9}/L, PT or PTT >1.5× control value, or fibrinogen level <1.0 g/L). With the exception of protamine to reverse the action of heparin, the nonstudy postoperative use of additional pharmacologic agents to reduce bleeding (antifibrinolytics: aprotinin, tranexamic acid, epsilon-aminocaproic acid; coagulation factor enhancers: desmopressin acetate) was avoided for the 24 hours in the study. The routine immediate postoperative use of low-dose acetylsalicylic acid (300 mg orally per day) for the protection of ACB-graft patency, and low-dose intravenous heparin (PTT <40) for antithrombotic protection of valve prostheses continued, as per usual protocol, when chest tube bleeding had diminished. Full therapeutic anticoagulation (heparin and/or warfarin) for mechanical prosthetic valves was instituted after chest tube removal at 24 to 36 hours postoperatively.

We calculated for each patient the total treatment expenditure on the basis of our hospital as the sum of the costs of topical hemostatic treatment and allogeneic products transfused. The costs are following: one box of Colgel powder, $110; 1 packet of Surgicel, $22; packed red blood cell, $44 per unit; and fresh frozen plasma, $13 for each unit.

Differences between the 2 groups of patients concerning hematologic and coagulative parameters were analyzed by the 2-tailed Student t test, while χ\textsuperscript{2} test was used to analyze the differences in surgical procedures performed. The difference of data about blood loss during the first 24 postoperative hours was analyzed by 2-way analysis of variance (ANOVA) (Colgel vs Surgicel group; time subdivided into 3-hour intervals) for repeated measures. The comparison of the blood loss during each 3-hour

interval between the Colgel and Surgicel groups was carried out by linear contrast, as well as the comparison of the total amount of chest drainage after the first 24 postoperative hours. The difference in total postoperative bleeding was analyzed by using the 2-tailed, unpaired Student t test because the chest tubes were removed after a variable of time. Cost of treatment was evaluated by Mann-Whitney U test.

The size of the study population had been selected based on the assumption that a total blood loss difference of at least 200 to 300 mL would be significant between the groups.

Results

During the study period (August 1999 and November 2001), 71 patients (8 women and 63 men) were included and randomized (Colgel group, n = 35; Surgicel group, n = 36). With respect to surgical procedures performed, the difference between the 2 groups was nonsignificant (P = .35) (Table 1). The mean (± SD) ages in the groups were 64 ± 6 and 62 ± 6 years, respectively (nonsignificant) (Table 2). Preoperative and postoperative hemoglobin concentrations, hematocrit levels, platelet counts, PT, and PTT were not significantly different between the 2 groups (Tables 3 and 4). No statistically significant differences were found in the dosage of heparin or protamine administered during the operations. There were 2 in-hospital deaths (1 from the Colgel group, 1 from the Surgicel group). One patient in the Colgel group who underwent repeat ACB died from a perioperative myocardial infarction 2 days after the operation. One patient in Surgicel group who underwent redo mitral valve replacement had a long and complicated postoperative course, including renal failure and sternal infection, and died 1 month after the operation.

Chest tube drainage in the first 24 hours was 373 ± 143 mL in the Colgel group and 571 ± 144 mL in the Surgicel group (P = .01). Total postoperative chest tube drainage was 423 ± 154 mL (range, 280-1100 mL) in the Colgel group and 677 ± 128 mL (range, 285-1350 mL) in the Surgicel group (P = .01). In addition, chest tube drainage was compared between the 2 groups every 3 hours after operation (Figure 1). Blood loss in the first 3 postoperative hours was significantly less in the Colgel group (132 ± 41 vs 228 ± 57 mL, P < .001). In the following 3-hour interval this significant difference persisted (67 ± 24 vs 121 ± 49 mL, P < .001). In the remaining 3-hour intervals, the blood loss in the Colgel group was lower compared with the Surgicel group, but the differences did not reach a significant level. In the Colgel group (n = 35), 6 patients received 28 units of packed red blood cells; in the Surgicel group, 20 patients received 120 units of packed red blood cells. In order to improve blood coagulation, 8 patients of the Surgicel group received a total of 46 units of fresh frozen plasma, while only 2 patients of the Colgel group received 8 units of fresh frozen plasma. The number of packed red blood cells as well as the total number of blood products required is just nonsignificant in the 2-tailed test (P < .07), while the difference in the 1-tailed test is significant (P < .03).
The cost of topical hemostatic agent treatment and the transfusion requirement were significantly lower in the Colgel group compared with the Surgicel group ($152 ± $22 vs $202 ± $29, respectively, \( P < .001 \)).

**Conclusions**

The high risk of bleeding in high-risk procedures necessitates the use of drugs to reduce postoperative bleeding and transfusion requirements. The study of Magovern and colleagues\(^6\) shows that the need for blood transfusion can be readily predicted from preoperative patient-related variables, ie, emergency and unstable preoperative patient status, factors associated with low preoperative red cell volume, and comorbid conditions and diseases. Although it is known that platelet activation and subsequent dysfunction increase with the duration of CPB, and procedures requiring long CPB times increase the risk of bleeding, in that study surgical factors such as the length of CPB longer than 105 minutes and redo sternotomy were only minor contributors.\(^6\) Also in our study, the duration of CPB was nonsignificant between the groups (105 ± 11 min and 111 ± 17 min in Colgel and Surgicel group, respectively), and we do not think it influenced our results. The aim of this study was to determine if microfibrillar Colgel powder was efficacious in reducing blood loss and transfusion requirements compared with oxidized cellulose (Surgicel) in cardiac operations associated with high risk of bleeding.

Microfibrillar collagen was initially described in 1969.\(^7\) It is a water-insoluble acid salt of bovine collagen prepared by a process that conserves the normal helical configuration of the tropocollagen molecule and most of the lateral bonding forces between these molecules. Because of its potential multiplicity of form, it was thought that it would be ideal as a vascular prosthesis. It was only when intense thrombogenic activity in these grafts was noted\(^8\) that its potential use as a hemostatic agent was considered.\(^8\,^9\) Topically used microfibrillar collagen adheres to the bleeding site and provides some tamponade hemostatic effect and initiates platelet activation and aggregation. It also reinforces the fibrin clot that formed.\(^8\,^9\)

Since that time, other reports indicate that it is probably effective as a local hemostatic agent.\(^10\,^11\) The bleeding surface is first sponged dry, then, with quick short bursts by squeezing the powder box, the hemostatic agent is blown onto the surfaces prone to bleeding.

Surgicel (oxidized cellulose) provides a lattice for natural clot formation.\(^12\)

In the present study, there was a significant difference between the Colgel and the Surgicel groups in terms of intraoperative blood loss and postoperative drainage volumes. (Chest tube drainage in the first 24 hours was 373 ± 143 mL in the Colgel group and 571 ± 144 mL in the Surgicel group) While 120 units of packed red blood cells were used for the Surgicel group, only 28 units were used for the Colgel group. The reduction in blood loss was significant in the initial 3 postoperative hours. It may be due to the early hemostatic effect of microfibrillar collagen.

In a previous report it was postulated that 27% of patients receive unnecessary blood transfusions.\(^13\) A recent publication has revealed the high costs of allogeneic blood transfusions.\(^14\) This includes the cost of collection, production, distribution, and delivery. The cost of bleeding includes not only the cost of drug/transfusion therapy, but also the materials and manpower of reoperations, prolonged intensive care, and the treatment of complications of large-volume blood-product transfusions. These costs are enormous in comparison to the cost of the drug therapy.\(^13\) At our institution, 1 box of Colgel powder is $110 and is quite reasonable when the reduction in blood loss provided by this agent is considered.

In conclusion, the easy application, low cost, and significant blood-loss reduction effect of microfibrillar collagen powder render this agent attractive for cardiac operations associated with high risk of bleeding.
