Aortic type A aortic dissection is a surgical emergency. After replacement of the ascending aorta, the arch and descending aorta often remain dissected, with a 40% risk of aneurysmal evolution at 5 years. Procedural dissections of arteries (coronary, renal, iliac) are treated with uncovered stents. Experimental studies on aortic dissections report suppression of false lumen and histologic cicatrization of stented uncovered stents. Experimental studies on aortic dissections report dissections of arteries (coronary, renal, iliac) are treated with stent implantations were achieved using intra-operative stenting and implantation of Djumbodis stents (Saint Côme Chirurgie, Marseille, France) (Figure 1). Stent implantations were achieved during complete circulatory arrest with deep hypothermia (12 patients) or partial circulatory arrest with antegrade cerebral perfusion (4 patients), according to the practices of the surgeons. Stent implantation took less than 2 minutes and was checked by direct vision (aortic arch) or radioscopy (descending aorta). Three patients were women (19%). Average age was 57.3 years (±10.6). Average EuroSCORE was 9.4 ± 2.9. Before the operation, the patients had important aortic regurgitation (n = 2), pericardial blood effusions (n = 4), myocardial infarctions (n = 2), stroke (n = 1), paraplegias (n = 2), and lower limb ischemia (n = 3). All patients had a dissection involving the whole aorta except for 1 patient without dissection of the descending aorta.

Patients and Methods

From November 9, 2000, to September 1, 2004, 16 patients with acute type A aortic dissections have been treated with combined procedures. They underwent replacement of the ascending aorta and implantation of Djumbodis stents (Saint Côme Chirurgie, Marseille, France) (Figure 1). Stent implantations were achieved during complete circulatory arrest with deep hypothermia (12 patients) or partial circulatory arrest with antegrade cerebral perfusion (4 patients), according to the practices of the surgeons. Stent implantation took less than 2 minutes and was checked by direct vision (aortic arch) or radioscopy (descending aorta). Three patients were women (19%). Average age was 57.3 years (±10.6). Average EuroSCORE was 9.4 ± 2.9. Before the operation, the patients had important aortic regurgitation (n = 2), pericardial blood effusions (n = 4), myocardial infarctions (n = 2), stroke (n = 1), paraplegias (n = 2), and lower limb ischemia (n = 3). All patients had a dissection involving the whole aorta except for 1 patient without dissection of the descending aorta.

Results

Duration of circulatory arrest was 28.9 minutes (±10.8) at 14°C to 23°C for complete circulatory arrest and 25 minutes (±12.5) at 25°C for partial circulatory arrest. Fifteen stents were implanted in aortic arches and 3 stents in descending aortas. There were 2 intraoperative deaths (12.5%), 1 caused by unstoppable hemorrhage and 1 caused by myocardial infarction despite an aorta-coronary bypass. Intensive care unit stay was 9.2 days (±6). Postoperative complications were respiratory (9/16), renal failure (6/16), and stroke (1/16). Two patients died after discharge, on days 15 and 16, and no autopsy was obtained. One patient died 95 days after the operation of a cerebral hemorrhage without cardiac or carotid etiology. After stenting of the arch, all supra-aortic trunks were patent on baseline computed tomographic (CT) scans. Median follow-up was 329 days (±310). Thirty-day mortality was 25% (4/16). Cumulate survival (Kaplan-Meier) was 77.9%.

Both preoperative and postoperative most recent (159 ± 96 days) CT scans were available for 13 of the 16 patients (2 intraoperative deaths and 1 unavailable CT scan). The patient without dissection of the descending aorta was excluded from the following comparisons. In all 12 remaining cases, aortic arches received a stent, whereas none of these descending aortas was treated. Comparison between preoperative and postoperative CT scans showed that the circulating false lumen disappeared in 8 of the stented aortic arches (66.7%) (Figure 2) and only 5 in the nonstented descending aortas (41.7%) (χ², P = .0384). The maximal diameters of the 12 stented aortic arches regressed −3.00 mm (±5.97) whereas the maximal diameters of the 12 nonstented descending aortas increased +1.17 mm (±3.71) (Student t test: P = .0070).

Comments

Despite the small number of patients, morbidity and mortality are in agreement with standard results in the literature and in our institutions for aortic dissection surgery. Technical feasibility is good, with correct durations of circulatory arrest and no major drawbacks concerning stent implantation taking less than 2 minutes.

Regarding pathophysiology, a favorable effect has been shown on false lumen occlusion and aortic diameter, with significant differences between stented and untreated segments in the same patients.

Mechanisms of action are different between uncovered stents and stent grafts. A stent graft occludes an entry and reduces flow and pressure in the false lumen, leading to its thrombosis. Here, the
uncovered stent joins the dissected layers despite entries. It contributes to aortic reinforcement and cicatrization, as shown experimentally.\textsuperscript{1,2} This cicatrization seems preferable to aortic replacement by a prosthesis or implantation of a stent graft because it preserves collateral arteries and may also restore perfusion in branches closed by dynamic occlusions.

Our conclusion is that this combined procedure is feasible and supports aortic restoration. We think such stenting should be extended to the whole dissected aorta.

We thank the Hospital of Rangueil (Toulouse, France), the Paul Sabatier University (Toulouse, France), la Università degli Studi (Parma, Italia), and the experimental surgery laboratory of Rangueil for their support.
