gradients on echocardiograms performed during these admissions were 23 and 26 mm Hg, respectively (Figure 1, C). Unfortunately, the patient died shortly thereafter from complications related to diabetes.

Discussion

Although this experience is limited to a single case, a low-dose rt-PA regimen with longer infusion duration is a promising approach for patients who are in hemodynamically stable condition and do not require rapid lysis. There may be a lower complication rate because of the significantly lower infusion rate, despite longer infusion duration. Patients should be monitored closely for adequate lysis. This includes daily echocardiography and laboratory evaluations (D-dimer, activated partial thromboplastin time, and fibrinogen). Fluoroscopy should be used to confirm leaflet motion. Further investigation is necessary to evaluate the short- and long-term efficacy and safety of this treatment strategy.

Arterial coronary revascularization failure as a result of coronary vasospasm

Marek Gwozdzieicz, MD, PhD, Martin Sluka, MD, and Marek Richter, MD, Olomouc, Czech Republic

Total arterial revascularization (TAR) is an option for the surgical treatment of ischemic heart disease. It provides better long-term patency than do venous aortocoronary bypasses. TAR seems to offer the most benefit to the patient when combined with the off-pump “aorta no-touch” technique.

Kobayashi and colleagues described a TAR technique that comprises two in situ internal thoracic arteries (ITAs) and a radial artery (RA) used as an I composite graft. They reported that to avoid the competition phenomenon in the graft, the distal end of the I composite should be placed on the right coronary artery (RCA) when this exhibits at least 80% stenosis.

Clinical Summary

A 76-year-old man was admitted to our department for elective coronary surgery. Preoperative angiography revealed triple-vessel disease with 40% left main coronary artery stenosis, 90% left anterior descending coronary artery stenosis, 90% diagonal artery stenosis, 80% circumflex artery stenosis, and at least 80% proximal RCA stenosis (Figure 1). Echocardiography showed good left ventricular function with no valve disease. The patient had extensive varicose veins on both lower extremities and negative results of an Allen test on both hands. A Doppler examination revealed RAs of good quality with adequate collateral flow.

Quadruple off-pump coronary bypass grafting was performed with the left anterior descending coronary artery bypassed individually by the left ITA. The diagonal artery, obtuse marginal artery,
and posterior descending branch of the RCA were sequentially grafted with a crossover I composite composed of the right ITA and left RA. Perioperative flow measurement with a transit-time flow meter showed blood flows of 27 and 71 mL/min in the left and right ITAs, respectively, with respective pulsatility indexes of 1.7 and 1.4.

The postoperative course of the patient was uneventful. Postoperative coronary angiography, performed on postoperative day 6 as part of the study protocol, revealed competitive flow in the distal segment of the I composite (Figure 2). All sutured anastomoses were patent. There was 40% stenosis in the proximal RCA, in contrast to at least 80% on preoperative angiography.

Discussion

Most coronary arteries onto which bypass conduits are sutured are not completely occluded and maintain some native blood flow. Sometimes the flow competition between a native artery and a bypass conduit may cause reversal of blood flow in the sutured graft, leading to its closure. This phenomenon has been especially noted in arterial bypass.4

TAR with composite grafts is becoming more popular, but many surgeons are concerned about blood flow competition when such grafts are placed in the right coronary system. Kobayashi and colleagues3 attempted to solve the problem of competition by suturing the distal end of a sequential I composite graft composed of the right ITA and RA to the RCA when the RCA exhibited at least 80% stenosis. For stenosis of the RCA less than 80%, they recommended grafting the RCA as the first in the sequence, side-to-side with the composite bypass. This graft orientation should decrease the risk of competition by maintaining the highest blood pressure wave in the anastomosis with the RCA.

Despite our adherence to the recommended rules, our patient had postoperative blood flow competition. This was caused, however, by a coronary vasospasm in the RCA that was misinterpreted as severe stenosis on the preoperative angiogram.

Our experience in this case demonstrates that it is critical for a surgeon who plans to perform the TAR with composite grafts to be aware of the possibility of coronary spasm, leading to overestimation of the degree of stenosis. This is especially important when the lesion is located in the proximal segment of the RCA, where spasm may be provoked by catheter insertion during coronary angiography.
