best of our knowledge, there are only 3 other reports of an accessory chordae tendinae located in the left atrium,10-12 with one report describing a prolapsing chordae through the mitral aperture11 and a fibrous band tethering the anterior mitral leaflet to the edge of the fossa ovalis.12 We present an unusual case of an accessory left atrial chordae tendinae associated with a partial cleft of the anterior mitral leaflet.

We thank Michelle J. Marge, RN, and Patricia M. Stevens, RDACS, of Christiana Hospital Center for Heart and Vascular Health for their invaluable assistance with image acquisition and processing.

Acute torsion of the left lower lobe caused by chronic traumatic hernia of the diaphragm

Yugo Tanaka, MD,a Wataru Nishio, MD,b Daisuke Hokka, MD,a Shiro Kawamura, MD,c Etsuji Shimada, MD,c and Shuuichi Okumura, MD,c Kobe, Japan

Lung lobar torsion is very rare and mostly occurs after lobectomy. We present a rare case of acute torsion of the left lower lobe caused by chronic traumatic hernia of the diaphragm that was successfully treated with resection of the left lower lobe and repair of a traumatic diaphragmatic rupture.

CLINICAL SUMMARY

A 42-year-old man was admitted to our hospital with back pain and high fever that had been increasing for a week. His medical history included only a motor vehicle accident that had occurred 22 years before, causing left diaphragmatic rupture. Repair of the diaphragmatic rupture was suggested...
at the time, but he refused because of lack of symptoms. After the accident, he had no trouble with daily life for 22 years. A chest radiogram on admission demonstrated a cystic lesion and opacity in the left lung field (Figure 1). Computed tomographic (CT) analysis showed a diffuse infiltrative shadow on an air bronchogram. CT also showed displacement of the intestines within the thoracic cavity and a cystic lesion with fluid collection in the distended left lung, which caused mediastinal shift (Figure 2). Bronchoscopy revealed a near-complete occlusion of the left lower bronchus. The patient was given a diagnosis of pneumonia, and antibiotics (doripenem, 1 g/d) were systemically administered. However, his laboratory data did not indicate improvement, and CT scanning revealed new fluid collection in the left lung. The patient was given a diagnosis of a left lung abscess, and emergency surgery was performed through a left posterolateral thoracotomy. The maximum diameter of the diaphragmatic rupture was 10 cm. The stomach, transverse colon, and small intestine were observed in the thoracic cavity through this rupture. The small intestine was strongly adhered to the left lower lobe and could not be detached, and therefore a part of the small intestine was resected. The congested left lower lobe was distended to twice its normal size, resulting in compression of the mediastinum and the left upper lobe, and the left lower lobe appeared to have torsion of 180° around the left inferior pulmonary vein. Left lower lobectomy and repair of the diaphragmatic rupture were performed. The patient recovered and was discharged on postoperative day 32. Pathologic examination revealed that the congested left lower lobe had diffuse gangrenous changes, and there was no remarkable finding in the resected small bowel.

DISCUSSION

Lung lobar torsion is a very rare disorder that has been reported to occur under 3 different circumstances as a complication of thoracic surgery, after blunt trauma, and as a spontaneous occurrence. Most cases of lung lobar torsion occur after thoracic surgery, and published reports have documented that the incidence of postoperative lung lobar torsion is 0.089% to 0.3%. To our knowledge, this is the first case report of lung lobar torsion caused by traumatic diaphragmatic rupture. Additionally, in this case more than 20 years passed before the onset of lung torsion, and it is a significant event to notify. Twenty-two years later, the patient had back pain and high fever a week before hospitalization, when lung torsion seemed to have developed.

With regard to the occurrence mechanism, it was quite complicated. A common inflammatory disorder in the left thoracic cavity, such as pneumonia, might be the trigger of all the events that occurred in this patient. Congestion of the lung and edema of the adhered tissue around the dislocated left lower lobe facilitated the development of lung torsion. A distinctly lobated left lung might also affect this occurrence.

Traumatic diaphragmatic rupture occurs in 1% to 7% of patients with major blunt trauma and in 10% to 15% of patients with penetrating trauma. Approximately 90% of diaphragmatic ruptures occur on the left side. Diaphragmatic rupture can result in ileus, respiratory distress, and cardiac insufficiency, and therefore repair of the diaphragmatic rupture should be performed as soon as possible after the occurrence.
Heparin-induced thrombocytopenia without thrombocytopenia

Frederick A. Tibayan, MD, Lawrence L. Leung, MD, Thomas A. Burdon, MD, and James I. Fann, MD

Heparin-induced thrombocytopenia (HIT) is a prothrombotic complication of heparin therapy mediated by antibodies that recognize platelet factor 4/heparin complexes and cause platelet activation and thrombin generation. Early recognition of HIT and treatment with non-heparin anticoagulants are essential in reducing thrombotic events, but diagnosis of HIT in patients postcardiac surgery may be confounded by thrombocytopenia because of bleeding, infection, drugs, or intraaortc balloon pump counterpulsation. Furthermore, postoperative thrombocytosis after cardiac surgery may mask platelet consumption because of HIT.

HIT typically suspected in patients with thrombosis or thrombocytopenia, usually defined as a platelet count less than 100,000/µL or relative decrease of 30% to 50%. We present a patient in whom HIT developed without thrombocytopenia after off-pump coronary artery bypass grafting.

CLINICAL SUMMARY

A 55-year-old man with coronary artery disease, diabetes mellitus, hyperlipidemia, and hypertension presented with an acute coronary syndrome. Coronary angiogram demonstrated multivessel coronary artery disease. He was placed on a heparin drip. The following day, he underwent a 2-vessel off-pump coronary artery bypass, during which he received 15,000 units of unfractionated heparin intravenously. He was given no heparin postoperatively. On postoperative day 2, his platelet count decreased from 213 to 168 K/µL.

On postoperative day 12, computed tomography of the chest, which was obtained to evaluate a fever, decrease in oxygen saturation to 93%, and mild increase in heart rate, demonstrated a saddle pulmonary embolus. The patient was otherwise asymptomatic. Lower-extremity ultrasound showed a thrombus in the left popliteal vein. The patient was anticoagulated with intravenous argatroban after obtaining specimens for and pending results of heparin-induced antibody and heparin-induced platelet aggregation tests. The results of the heparin-induced antibody and heparin-induced platelet aggregation were positive. The transition to oral anticoagulation with warfarin was made, and the patient was discharged on postoperative day 28. Follow-up computed tomography before discharge demonstrated significant diminution of the pulmonary embolus. He remained well at the 3-month follow-up.

DISCUSSION

HIT is a life-threatening complication in patients undergoing cardiac surgery. Early detection and anticoagulation may limit morbidity caused by HIT, but the diagnosis of HIT in patients undergoing cardiac surgery is confounded.
