Endovascular repair of aortic arch lesions in high-risk patients or after previous aortic surgery: Midterm results

Ludovic Canaud, MD, Kheira Hireche, MD, Jean-Philippe Berthet, MD, Pascal Branchereau, MD, Charles Marty-Ané, MD, PhD, and Pierre Alric, MD, PhD

Objective: The aim of this study was to assess the short- and midterm results after endovascular repair of the aortic arch in high-risk patients or after previous aortic surgery.

Methods: From November 1998 to November 2008, 57 thoracic stent grafts were implanted in 44 patients (sex ratio, 4.5; mean age, 66.5 ± 16.5 years) for aortic arch repair (zone 0 to 2 according to the arch map proposed by Ishimaru) of 19 degenerative aneurysms, 12 traumatic transections of the aorta, 8 complicated aortic dissections, 4 postcoarctectomy aortic pseudoaneurysms, and 1 penetrating atheromatous ulcer. All patients were considered to be at high surgical risk owing to serious comorbidities (American Society of Anesthesiologists score ≥ III [79.5 %]) or previous aortic surgery. Endovascular repair was performed in an emergency setting in 27.3 % (n = 12) of the patients. Thirty-four underwent a hybrid technique with supra-aortic debranching and simultaneous or staged endovascular stent grafting. Debranching was performed to provide an adequate proximal aortic landing zone, in 28 patients by a cervical approach and in 6 patients by a sternotomy approach.

Results: The technical success rates for aortic zone 0 patients (n = 6), zone 1 patients (n = 4), and zone 2 patients (n = 34) were, respectively, 100%, 100%, and 97%. The 30-day mortality rate was 20.4%. The actuarial survival was 70% over a mean follow-up of 29.9 months. The rate of stroke was 6.8%. Two (4.5%) cases of paraplegia were observed, 1 of which was reversible after cerebrospinal fluid drainage. The rate of endoleak was 15.9% (n = 7): 3 type I, 3 type II, and 1 type III. There were no cases of device migration, but 1 stent-graft collapse occurred 20 days after exclusion of an aortic traumatic transection.

Conclusion: Hybrid endovascular aortic arch reconstructions, although some of these adjunctive procedures remain major operations, provide attractive alternatives for treating aortic arch lesions in high-risk patients who would otherwise be unsuitable for open repair, with acceptable primary results and encouraging midterm efficacy to prevent rupture. (J Thorac Cardiovasc Surg 2010;140:52-8)

Conventional surgical repair of aortic arch diseases requires arch replacement during deep hypothermic circulatory arrest for cerebral protection. Mortality and morbidity associated with transverse aortic arch replacement in the standard risk population has decreased over the past decades as various modifications of surgical technique have been introduced. Despite these recent advances, reconstruction of the aortic arch remains a challenge, particularly in elderly patients, in patients requiring emergency repair, or in those with major pre-existing comorbidities. Furthermore, many of these patients are deemed unsuitable for open repair.

Aortic arch diseases or extension of all descending thoracic aortic pathologic conditions toward the major aortic side are often deemed unsuitable for endovascular repair owing to the close proximity of the supra-aortic trunks. A combined endovascular and open approach has therefore recently been adopted as a valuable alternative, consisting in supra-aortic debranching and revascularization followed by stent-graft deployment. Debranching is performed to provide an appropriate landing zone for the stent graft and to preserve perfusion to the supra-aortic trunks.

Endovascular repair presents a particular challenge owing to the involvement of supra-aortic trunks, the anatomic curvature of the arch, the high blood flow in the area, and substantial movement of this portion of the aorta at each heartbeat.

The aim of this study was to assess short- and midterm results of hybrid endovascular aortic arch repair in patients deemed unsuitable for open surgery (American Society of Anesthesiologists [ASA] score ≥ 3) or in patients with previous aortic arch repair.

METHOD

Patients

From November 1998 to August 2008, 44 patients required stent-graft landing in the aortic arch: zone 0 to 2 (aortic arch map proposed by Ishimaru1). Among them, 34 underwent a hybrid technique with supra-aortic debranching and simultaneous or staged endovascular stent grafting to treat
complex aortic arch disease. There were 36 men and 8 women (mean age, 66.5 ± 16.5 years; range, 19–89 years).

All patients were unfit for open surgery because of serious comorbidities (ASA ≥ III, n = 35, 79.5%) or a history of thoracic aortic open repair (n = 11, 25%). Furthermore, 12 (27.3%) operations were performed in an emergency setting.

Nineteen (43.2%) patients had a degenerative aneurysm, 4 of which had ruptured. Eight (18.2%) patients had a complicated aortic dissection (6 dissecting aneurysms, 1 rupture of acute type B dissection, and 1 proximal type I endoleak, which arose 7 years after endovascular repair of a painful type B dissection). Twelve (27.3%) patients had a traumatic transection of the aortic isthmus; 5 of them were in hemodynamically unstable condition. Four (9%) patients had postcoarctectomy aortic pseudoaneurysm and 1 (2.3%) patient had a ruptured penetrating atherosclerotic ulcer. Further preoperative data are shown in Table 1.

All 44 patients were considered to have an inadequate proximal landing zone for aortic arch stent-graft insertion, but only 34 (77.3%) of them were divided into 3 groups according to the proximal landing zone: 0, 1, or 2 artery (LSA) without prior revascularization was required to allow a swift cervical approach in 28 patients and through a median sternotomy in 6 patients. Debranching and revascularization—via a cervical approach in 28 patients and through a median sternotomy in 6 patients. Regarding the 10 remaining patients, the coverage of the left subclavian artery (LSA) without prior revascularization was required to allow a swift procedure owing to the hemodynamically unstable state. Patients were divided into 3 groups according to the proximal landing zone: 0, 1, or 2 (Figure 1). Zone 0 was involved in 6 patients, zone 1 in 4 patients, and zone 2 in 34 patients.

Surgical Approach

All procedures took place in the operating room with the patient under general anesthesia. Debranching procedures were performed before the deployment of the stent grafts. Endovascular repair was performed in the same operating setting in 24 (54.5%) patients.

Debranching and revascularization of supra-aortic trunks with a prosthetic graft was performed in all zone 0 cases through a median sternotomy; in zone 1 patients, extra-anatomic revascularization of the LCCA and LSA was performed with an LCCA transposition in the BT or with a carotid–carotid bypass, followed by a left carotid–subclavian transposition. Regarding zone 2 patients, revascularization of the LSA was performed with an LCCA transposition in the BT or with a carotid–subclavian bypass transposition.

The mean number of stent graft used was 1.3 ± 0.6 (range 1–3) and the mean stent-graft diameter was 35.6 ± 5.4 mm (range 24–40 mm).

Endovascular Repair

All patients underwent contrast-enhanced computed tomographic scan to assess the feasibility of endoluminal repair, sizing of stent grafts, and implant strategy. Thirty-one (70.4%) patients had an additional preoperative aortic arch angiography. Suitable morphology for stent-graft placement requires a proximal aortic neck length of at least 15 mm. Measurements from preprocedural imaging data were used to select the appropriate diameter and length of the stent graft. Devices were oversized by 10% to 20% greater than the minor axis of the aortic neck to provide sufficient radial force for adequate fixation. All patients underwent preoperative computed tomographic scan of the femoral, iliac, and supra-aortic arteries to evaluate access vessels and supra-aortic trunks.

Prophylactic use of cerebrospinal fluid drainage to prevent spinal cord ischemia was not used. The endovascular devices were delivered via the common femoral artery. A 260-cm, 0.035-inch guidewire (Terumo Medical Corporation, Tokyo, Japan) was placed, via the common femoral artery, under fluoroscopic control (digital C-arm) into the ascending aorta; a 5F calibrated pigtail catheter was advanced into the ascending aorta over the guidewire. This pigtail catheter was used to exchange the guidewire for an extra-stiff guidewire (Lunderquist; Cook Inc); angiography was performed through a 4F pigtail catheter advanced into the right subclavian artery through the right brachial artery. The stent graft was deployed under fluoroscopic control. A baseline angiogram was performed before and after stent-graft deployment to confirm proper position of the stent graft and complete exclusion of the lesion. Ballooning was performed selectively.

Follow-up and Statistical Analysis

Follow-up surveillance was performed with serial computed tomographic scans at 1 week, then at 3, 6, and 12 months, and annually thereafter. Outcomes were analyzed by Kaplan–Meier life table analysis.

RESULTS (TABLES 2–5)

Overall

Forty-four patients were treated for lesions involving zone 0 to 2 of the aortic arch. The mean proximal aortic diameter was 29.8 ± 4.7 mm. The mean distal aortic diameter was 24.8 ± 4.5 mm. The mean proximal aortic neck length was 19.5 ± 4.7 mm. The mean distal aortic neck length was 20 mm in 2 patients and more than 30 mm in the remaining patients. The mean length of the covered aorta was 180 ± 92.3 mm. The mean diameter of the aneurysms was 64.5 mm ± 12.6 (range, 50–102 mm).

Technical success was obtained in 97.7% of the patients. A patient treated for a ruptured aneurysm had an intraoperative proximal type I endoleak left untreated. The 30-day mortality rate (Table 2) was 20.4% (9/44). The actuarial survival was 70% over a mean follow-up of 29.9 ± 30.1 months (Figure 2). The rate of cerebrovascular accident was 6.8%: 1 fatal stroke, 1 transient ischemic accident, and 1 intracranial hematoma from which the patient completely recovered. Two (4.5%) cases of paraplegia were observed, 1 of which was reversible after cerebrospinal fluid drainage. The rate of endoleak was 15.9% (n = 7): 3 (6.8%) type I, 3 (6.8%) type II, and 1 (2.2%) type III. There were no instances of device migration, but 1 stent-graft
According to the Zone

**Zone 0.** Debranching and revascularization of the supra-aortic trunk with a prosthetic graft was performed in 6 cases through a median sternotomy followed by endovascular stent grafting. Technical success was obtained in all. In a case of acute aortic arch angulation, establishment of a brachiofemoral wire, which is held on each end to straighten the angulated aortic arch. Stabilizing the route and advancement of the delivery sheath, allowed the deployment of the stent graft in zone 0. Early postoperative complications requiring secondary surgical intervention were sternal disunion and cardiac tamponade in 1 case each. The 30-day mortality rate was 0%. One case of transient paraplegia and one transient ischemic accident were observed. One type II endoleak was observed that resolved spontaneously. One case of retrograde type A dissection occurred on the fourth postoperative day after aortic clamping; the patient underwent immediate surgical conversion with ascending aortic replacement under circulatory arrest and suture between the prosthetic graft and the stent graft, which resulted in a favorable outcome. There were no instances of device migration.

**Zone 1.** Four patients underwent LCCA revascularization and carotid–subclavian transposition followed by endovascular stent grafting. Technical success was obtained in all the patients. One iliac artery rupture occurred peroperatively and was treated by implantation of a covered stent: Wallgraft (Boston Scientific, Natick, Mass). One patient died on the 15th postoperative day related to a massive myocardial infarction. No instances of cerebrovascular accident, paraplegia, or endoleak were observed. There was no device migration.

**Zone 2.** Twenty-four patients underwent a carotid–subclavian transposition, and in the 10 remaining patients, the ostium of the LSA was deliberately covered because the patients were in hemodynamically unstable condition (3 ruptured aneurysms, 5 transections of the aortic isthmus, 1 ruptured type B dissection, and 1 penetrating atheromatous ulcer). Technical success was obtained in 97% of the 34 patients. An 86-year old man, treated for a ruptured aneurysm, died with a proximal type I endoleak left untreated. This endoleak was related to an incomplete proximal sealing owing to a lack of adequate oversizing: at this time, the largest available commercial thoracic device had a diameter of 40 mm, and the proximal neck was 39 mm in diameter. Accidental coverage of the BT occurred in 1 patient. The inflow was rapidly recovered by transcortid insertion of a self-expanding stent with a high radial force alongside the thoracic endograft. After 1 year of follow-up, the stent placed in the LCCA completely collapsed, leading to a 70% stenosis of the LCCA and BT. Therefore, an ascending aorta to BT and LCCA bypass was performed through a median sternotomy. Accidental coverage of the LCCA occurred in 3 patients. In 1 case, the stent graft was pulled distally by traction by low-pressure inflated balloon. Regarding the remaining patients, the inflow was recovered by stenting of the left common artery. One iliac artery rupture occurred peroperatively and was treated by implantation of a covered stent: Wallgraft (Boston Scientific). One postoperative cervical hematoma required secondary surgical intervention.

One (2.9%) case of paraplegia was observed. The rate of cerebrovascular accident was 5.8%: 1 fatal stroke and 1 intracranial hematoma from which the patient completely recovered. The 30-day mortality rate was 23.5%. The causes of death were heart failure in 3 patients, multiple organ failure in 1 patient, stroke in 1 patient, postoperative acute rupture of the aorta in a patient treated for a ruptured acute aortic type B dissection, hepatic failure in a cirrhotic patient, and finally failure of exclusion (type I endoleak) in 1 patient.
The rate of endoleak was 17.6% (n = 6): 3 type I endoleaks, 2 type II endoleaks, and 1 type III endoleak. In 2 patients, a type I endoleak was treated by proximal implantation of a second stent graft after the fulfillment of carotid–carotid bypass to provide an adequate proximal landing zone. Regarding type II endoleaks, 1 patient underwent LSA embolization that allowed complete exclusion of a ruptured aneurysm; the second endoleak spontaneously resolved. A type III endoleak was successfully managed by deployment of a second stent graft. There was no device migration, but a stent-graft collapse occurred 20 days after exclusion of a traumatic transection of the aorta. The stent graft was...

The Journal of Thoracic and Cardiovascular Surgery • Volume 140, Number 1
successfully re-expanded by deployment of a second stent graft. For 2 of the 10 patients in whom the ostium of the LSA was deliberately covered, an LSA–LCCA transposition was secondarily performed to treat vertebrobasilar insufficiency.

**DISCUSSION**

Repair of the aortic arch is a surgical dilemma, mainly owing to the adverse neurologic sequelae ranging from 1% to 10%. The surgical outcome has been improving lately. However, a recent report indicated that the 30-day mortality after aortic arch surgery in the standard risk population (renal failure 5%, diabetes mellitus 7%, prior cerebrovascular accident 9%, prior myocardial infarction 7%) ranges from 4% to 28.6% according to the adjunctive measures for cerebral protection used (profound hypothermia and antegrade or retrograde cerebral perfusion) and to mode of presentation (elective or emergency). Furthermore, many patients are deemed unsuitable owing to serious comorbidities. As a consequence, a less invasive approach would be even more favorable to patients.

Since the first report by Dake and associates, endovascular management has emerged during the past decade as a valuable treatment modality for descending thoracic aortic diseases and was recently proposed for delicate anatomic regions such as the aortic arch. Stent grafting the aortic arch brings new challenges: stent grafts are subject to greater dynamic aortic motion than in the abdominal segment related to its curved configuration. Furthermore, physicians have to deal with the branches of the aortic arch to provide an adequate proximal landing. Recent reports have demonstrated the technical feasibility of complete or partial debranching of the supra-aortic trunks associated with endovascular repair of the aortic arch.

ASA, American Society of Anesthesiologists.

In patients with a short proximal aortic neck, the LSA can be overstented to effectively exclude thoracic aneurysms. In case of overstenting of the LSA, an LSA–LCCA transposition should be preferred inasmuch as efficacy and long-term patency are better as compared with the outcome of bypasses. In an emergency setting, coverage of the LSA can be performed without prior revascularization if mandatory for adequate anchoring. LSA revascularization can be proposed in a second operative time either in case of left arm ischemia or in case of vertebrobasilar insufficiency. In elective cases, eventual coverage of the LSA should be discussed before endovascular repair. A meta-analysis of Peterson and coworkers showed that morbidity relative to LSA revascularization before stent-graft repair was lower than morbidity in cases of LSA coverage without revascularization (3% vs 23%). Furthermore, Buth and associates assessed the significance of clinical factors that potentially influenced the occurrence of neurologic sequelae during endovascular repair of the thoracic aorta: perioperative paraplegia or paraparesis was significantly associated with blockage of the LSA without revascularization. Maintaining normal perfusion of the ipsilateral vertebral artery allows the prevention of ischemia of the brainstem and, furthermore, preserving major collaterals of the vertebral artery that contribute to spinal blood flow protects against spinal cord ischemia when multiple intercostal vessels are covered during thoracic endovascular repair. Revascularization of a dominant left vertebral artery and/or associated lesions of other supra-aortic arteries justifies LSA revascularization to reduce the rate of postoperative cerebral vascular accidents.

Patients who have thoracic aneurysms with a short neck distal to the LCCA are best treated with total coverage of the LCCA. The potential sources of inflow in these cases include the right common carotid, subclavian, axillary, or femoral vessels. The simplest reconstructions for this purpose are LCCA transposition in the BT or carotid–carotid bypass, which is performed through a cervical approach.

Patients with arch aneurysms that involve the portion of the arch adjacent to the BT require total aortic arch debbranching to obtain an adequate proximal landing zone. Total arch transposition by a sternotomy approach, with partial crossclamping of the ascending aorta, leads to a longer proximal landing zone. This is tolerated by even fairly sick patients from a cardiovascular standpoint. The quality of the
ascending aorta is an important factor to consider. The aorta must not be severely calcified or aneurysmal.

Our preference is to perform simultaneous debranching procedures. The advantage is that in case of a failure of exclusion, an open surgical treatment option can be proposed: external banding of the proximal landing zone or an additional debranching procedure. Furthermore, rupture of the aneurysm may occur after the debranching procedure, while the patients are waiting for staged endovascular treatment. Most of the staged procedures were performed at the beginning of our experiences. However, simultaneous procedures often require much longer operating times and are more stressful for the patient and the surgeon. Additionally, renal function may be more affected by simultaneous procedures because of surgical blood loss and contrast load.

Overall results of our retrospective study indicate a high rate of clinical success (97.7%), a low rate of permanent paraplegia (2.2%) or paraparesis (2.2%), and a low rate of stroke (6.8%). Considering the preoperative clinical status of our patients, 79.5% of our patients were in critical condition at the time of surgery (ASA > III) or had an history of thoracic aortic open repair (n = 11, 25%). Furthermore, 27.3% were treated in an emergency setting, which might explain the high mortality rate observed (20.4%).

Retrograde dissection is an issue. The reported incidence of retrograde dissection after thoracic stent-graft repair seems to be about 1% to 2%.12,13 This complication arises from wire manipulation in the aortic arch during the endovascular procedure, from the lack of conformability of most currently available thoracic stent grafts to the aortic curve in an angulated aortic arch that may injure the aortic wall, from excessive oversizing, especially in case of acute type B dissection,13 and from aortic wall stress related to balloon dilations. The design of the stent graft also has been involved (presence or absence of a proximal bare stent segment); the rate of retrograde dissection appears similar for both the TAG and the Talent thoracic stent grafts.12

Atheroembolic complications remain challenging during aortic arch repair, even in case of endovascular repair. Careful manipulation of central vessels as well as keeping cross-clamp times short to avoid exceeding the ischemic frame of cerebral tissue is mandatory for success. Furthermore, the wires in the aortic arch have to be manipulated cautiously to avoid soft plaque detachment.

Other endovascular approaches have also been reported. Chuter and associates14 reported the use of a modular branched stent graft for endovascular repair of aortic arch. The disadvantages of this modular approach are the potential for subsequent disassembly, the required time to manufacture and deliver such custom-made stent grafts for urgent cases, and the high cost of this kind of modular devices. Criado15 reported a percutaneous endovascular technique by retrograde puncture of the LCCA to deal with stent-graft coverage of the origin of the supra-aortic trunks during thoracic endovascular aortic repair: “interposition” of a bare metal stent between a thoracic stent graft and the aortic wall allows preservation of arch branch patency during thoracic endovascular aortic repair and stenting by focally displacing the stent-graft device. This alternative does not appear adequate with regard to the uncertain durability of this option and should only be considered in case of preoperative inadvertent coverage of the supra-aortic trunks. Inoue and colleagues16 have demonstrated the feasibility of using unibody stent grafts to repair the aortic arch. However, a high rate of embolism was associated with this technique and is probably related to the complexities of multibranched unibody stent-graft deployment.
Current thoracic stent grafts do not meet the needs. Thoracic stent grafts are designed for the descending thoracic aorta, which is straight, and thus most of them are unable to conform to the inner curve of the aortic arch. Furthermore, discrepancy in the diameter of the proximal landing zone (ascending aorta) and distal landing zone (descending thoracic aorta) is often observed. Improvements of the stent-graft design are required with more flexible and tapered designs or with multi-branched modular stent grafts.

Kouchoukos and associates reported results of the “clam-shell” repair of chronic dissection; 46 of 51 patients had prior operations in the standard risk population. The overall mortality rate was 3.9%. All had replacement of the ascending aorta and entire arch. A few centers of excellence are reporting excellent outcomes of arch repair with a history of thoracic aortic surgery. However, it is difficult for other centers to reproduce as good results as reported by these centers of excellence. In 4 of the largest recently reported series of elephant trunk procedures, the cumulative mortality for the 2 procedures and from deaths in the interval between the 2 procedures (commonly from aortic rupture) exceeded 20%. In our experience, 3 of the 11 patients with a history of thoracic aortic repair were treated in an emergency setting for a ruptured aneurysm. None of the patients treated in an elective setting with prior thoracic aortic repair died after a mean follow-up of 29.9 months. In this subgroup, the estimated survival at 1 year is 100%.

The chief limitation of our study is the relatively small number of patients, which affects the power of the study. Our study was not powered to detect differences in clinical outcomes.

Although the endovascular option can provide distinct advantages over conventional open surgery for repair of aortic arch aneurysm, it is clear that the arch is the most challenging area for stent-graft placement. Endovascular aortic arch reconstruction, although some of these adjunctive procedures remain major operations, provides an attractive alternative for treating aortic arch diseases in high-risk patients who would otherwise be unsuitable for open repair, with acceptable primary results and encouraging midterm efficacy to prevent rupture. This technique further expands the aortic territory that can be grafted. Until branched aortic stent grafts become available, debranching techniques combined with aortic stenting provide the optimal approach for the management of aortic arch lesions in high-risk patients.
