a graft-assisted anastomosis between the ascending aorta and the supraceliac abdominal aorta.2 In our patient, a graft was implanted between the ascending and descending aortas.

To avoid uncontrolled bleeding, there are 3 aspects that must be focused on perioperatively. First, all ductal tissue must be aggressively removed. Otherwise the anastomosis between the graft and the aorta will be susceptible to bleeding. Second, the anastomosis should be free of tension. Careful study of CT scans and better preoperative preparation are helpful to achieve complete dissociation of the descending aorta. More important, implanting a conduit will assist in reducing the tension. Third, pressuring hemostasis is effective when uncontrolled bleeding occurs. A bandage was placed with a little pressure on the stoma and thoracic cavity. One of the tips was placed out of the thoracic cavity. The bleeding volume was 900 mL on postoperative day 1 and 350 mL on postoperative day 2. The hemostasis technique was an effective way to manage uncontrolled bleeding in this patient.

Because of the pulmonary artery aneurysm and the difficulty in exposing the PDA and descending aorta in this patient, we used the left femoral artery to perfuse the lower body. With these methods, circulatory arrest of the lower body was avoided and the risk of neurologic complications was minimized. The postoperative course was uneventful. The patient was discharged and has fully recovered.

A new concept for correction of systolic anterior motion and mitral valve regurgitation in patients with hypertrophic obstructive cardiomyopathy

Joerg Seeburger, MD, Jurgen Passage, MBBS, Michael A. Borger, MD, PhD, and Friedrich Wilhelm Mohr, MD, PhD, Leipzig, Germany

In patients with hypertrophic obstructive cardiomyopathy (HOCM), systolic anterior motion (SAM) of the anterior mitral leaflet (AML) can occur as a result of acceleration of flow in the left ventricular outflow tract. In addition, relative shortening of the chordae tendineae may reduce AML mobility and contribute to the generation of mitral regurgitation (MR). We present a new concept for correction of SAM and MR in patients with HOCM and restricted AML movement.

METHODS

The procedure consists of 2 stages, septal myectomy followed by complete resection and replacement of all AML chordae with the loop technique1,2 (Figure 1). Myectomy enlarges the left ventricular outflow tract and reduces the risk of SAM. Resection of the foreshortened chordae to the AML and replacement with longer neochordae also reduces the risk of residual postoperative SAM and subsequent MR.

RESULTS

Since March 2008, 4 consecutive patients with HOCM, severe SAM, and evidence of restricted AML movement have been operated according to this new concept. In all cases, loops (average 8 per patient; range, 7–9) measuring 26 mm in length were implanted from both papillary muscles to the free margin of the AML. A flexible posterior band was implanted in 3 patients. Perioperative course was uneventful, with no major adverse events in all cases. Predischarge control showed no evidence of SAM and/or MR.
CONCLUSIONS

Septal myectomy represents the surgical standard of care for HOCM.\textsuperscript{1} For cases of concomitant SAM, several other techniques have been described.

Chordae replacement has been pursued by Rankin and colleagues,\textsuperscript{3} with 1 patient undergoing complete resection of the anteromedial papillary muscle and subsequent implantation of neochordae to the posterolateral papillary muscle. Although this technique was successful, it would probably distract the subvalvular apparatus and AML as a result of diagonal forces toward the posterolateral muscle. AML extension with an oval pericardial patch in combination with myectomy has been described by Kofflard and associates.\textsuperscript{4} They presented long-term results of 20 patients, with sustained improvement in functional status and attenuation of MR and SAM. Schoendube and colleagues\textsuperscript{5} described an even more aggressive procedure consisting of reconstruction of the subvalvular apparatus by mobilization and partial excision of papillary muscles. They reported excellent functional improvement with relief of left ventricular outflow tract obstruction in 58 patients.

These techniques are all alike with regard to the use of myectomy but differ with regard to the leaflet procedures. As our initial experience shows, resection of foreshortened AML chordae with implantation of longer neochordae (loop technique) is highly effective (Figure 2). This new concept may represent an important treatment option for patients with the combination of HOCM, SAM, and restricted AML movement.

**FIGURE 1.** Benefits of myectomy in widening left ventricular outflow tract (LVOT) diameter (A), of longer neochordae for further extension of left ventricular outflow tract diameter (B), and of neochordae for correction of mitral regurgitation by relocating anterior mitral leaflet (AML) toward annular plane (C). AV, Aortic valve; LA, left atrium; PML, posterior mitral leaflet; IVS, interventricular septum; LV, left ventricle.

Surgical repair of aortopulmonary window associated with interrupted aortic arch: Long-term outcomes

Igor E. Konstantinov, MD, PhD, Norihiko Oka, MD, PhD, Yves d’Udekem, MD, PhD, and Christian P. Brizard, MD, Melbourne, Australia

Association of aortopulmonary window (APW) with interrupted aortic arch (IAA) is very rare. Only 3.5% to 4.2% of patients with IAA have APW.1,3 Thus the cumulative experience with this combination of lesions is limited to isolated case reports. The largest multi-institutional study of 20 patients operated on from 1987 to 1997 demonstrated survival of 91%, 86%, and 84% at 1, 5, and 10 years, respectively.2 Furthermore, competing risk analysis estimated that at 5 years after repair, 51% had arch reintervention, 6% had pulmonary artery reintervention, and only 43% were alive without reintervention.2 Herein we report the long-term outcomes of 5 patients from a single institution and describe our aortic mobilization and advancement technique, which resulted in a low reintervention rate in this rare subgroup of patients.

CLINICAL SUMMARY

Cardiopulmonary bypass is established through a median sternotomy. Patients were cooled to a mean of 19°C. Mean cardiopulmonary bypass time was 69 minutes. Mean circulatory arrest time was 27 minutes. Mean aortic cross-clamp time was 40 minutes. The aortic arch, APW, and descending aorta were dissected (Figure 1, A). The descending aorta was extensively mobilized, and all ductal tissues were removed during circulatory arrest with cerebral perfusion (Figure 1, B). The thick-walled ductal tissues were resected until the normal thin wall of the aorta appeared. The extent of the mobilization of the descending aorta was evolved to our currently used technique, in which at least 3 pairs of intercostal arteries are divided to ensure proper mobilization of the...
