Early surgical therapy of infective endocarditis in children: A 15-year experience

Pirouz Shamszad, MD, Muhammad S. Khan, MD, Joseph W. Rossano, MD, and Charles D. Fraser, Jr, MD

Objectives: Infective endocarditis is rare in children but potentially carries high mortality and morbidity. Few data exist regarding surgical therapy and the associated outcomes in children with infective endocarditis. The aim of the present study was to describe the characteristics and outcomes of children undergoing surgery for infective endocarditis.

Methods: A retrospective review of all patients aged 21 years or younger diagnosed with definitive infective endocarditis at a single center from 1996 to 2010 was performed.

Results: Of 76 identified patients with infective endocarditis (median age, 8.3 years; 73.9% boys), 46 patients (61%) required surgical intervention. *Staphylococcus aureus* was most commonly isolated (18 patients, 24%) followed by *Streptococcus* (17 patients, 22%). Common surgical indications included severe valvular insufficiency in 13 patients, septic embolization in 12, concomitant severe valvular insufficiency and ventricular dysfunction in 9, persistent vegetations in 9, and persistent bacteremia in 3. Although early surgery was performed within 7 days of diagnosis in 35 patients (76%), 25 (54%) underwent surgery within 3 days or less. The factors associated with surgery included the presence of ventricular dysfunction, left-sided vegetation, severe valvular insufficiency, septic embolization, and *S aureus*. Surgery within 3 days or less was associated with the presence of ventricular dysfunction and *S aureus*. Native valve repair was performed in 50% of patients with native-valve disease. Postoperatively, no septic embolization events occurred and recurrence was low (2%). The 1-, 5-, and 10-year survival was 98% ± 2%, 90% ± 8%, and 81% ± 11%, respectively.

Infective endocarditis (IE), although relatively uncommon in children, is a serious infection associated with significant morbidity and mortality. Effective treatment of IE typically involves prolonged medical therapy with intravenous antibiotics, which can be combined with surgical therapy in some patients. Often in complicated IE, the decision between surgical versus medical therapy can be complex.

The presence of congenital heart disease represents a significant difference between adult and pediatric populations and affects the epidemiology, treatment, and outcomes of IE. Although surgical indications for IE have been outlined by the American Heart Association and endorsed by the American Academy of Pediatrics, the recommendations were determined from adult data, and generalization to the pediatric population might not be appropriate. Data describing the surgical experience in children with IE are sparse, and, as such, no pediatric-specific surgical indications have been published to date. It is notable that some centers, particularly those in developing countries where IE is more common, have adopted a strategy of aggressive, early intervention (Drs Parvathi and Krishna Iyer, personal communication, 2010).

Early surgical intervention during the acute phase of infection has been associated with good outcomes in adults. It is also very likely that optimal surgical timing is likely crucial for improved outcomes in children. However, to our knowledge, no data have examined the effect of surgical timing on the outcomes in children.

To better understand the surgical indications, timing, and outcomes of children with IE, we aimed to describe the 15-year surgical experience at a large, tertiary-care children’s hospital.

METHODS

Patient Selection and Variables

We conducted a retrospective review of the pediatric cardiology and cardiovascular surgery databases to identify patients diagnosed with IE at...
Abbreviations and Acronyms
IE = infective endocarditis
IQR = interquartile range

Texas Children’s Hospital from January 1996 to December 2010. The Baylor College of Medicine institutional review board approved the study. All available medical records, laboratory results, imaging reports, and surgical reports were reviewed. All patients 21 years old or younger who were diagnosed with definitive IE, as outlined by the modified Duke criteria, were included. In cases of recurrent IE, only the index case was included in the present analysis. A history of congenital heart disease, previous cardiac surgery, or the presence of prosthetic graft material was not considered a criterion for exclusion. To improve subject homogeneity, patients with probable endocarditis, as outlined by the modified Duke criteria, were not included in the present study.

Definitions
The patients were categorized for analysis into either the medical or surgical group according to the need for surgery as a part of their IE treatment regimen. The surgical group was defined by the need for surgery for acute IE within 6 weeks of starting appropriate intravenous antimicrobial therapy.

Patients with congenital heart defects were grouped into 3 categories: lesions with left to right shunting, lesions affecting the right ventricular outflow tract or requiring the creation of a right ventricle to pulmonary artery conduit for repair, and lesions affecting the left ventricular outflow tract, including bicuspid aortic valve. Estimation of valvular insufficiency and cardiac function were taken directly from the echocardiographic data. The degree of valvular insufficiency was qualitatively determined by the reporting cardiologist. Ventricular dysfunction was quantitatively defined as an ejection fraction less than 55% or a shortening fraction less than 2 Z-scores for age and size when the ejection fraction was not available.

Statistical Analysis
The data were not normally distributed. Descriptive statistics are reported using the median and interquartile range (IQR) for scale variables and proportions for categorical variables. Univariate analysis of categorical variables was performed using the Pearson chi-square test or Fisher’s exact test. The multivariate factors associated with surgical timing were determined by binary logistic regression analysis and are expressed as odds ratios with 95% confidence intervals. All survival analyses were performed using Cox regression analysis and are expressed as hazard ratios and 95% confidence intervals. Kaplan-Meier survival analysis was used to determine the 1-, 5-, and 10-year survival. The 2-tailed test of significance was used in all statistical analyses.

RESULTS
Patient Population
A total of 76 patients at a median age of 8.3 years (IQR, 2.1-14.4 years) who met the inclusion criteria were included in the present study. Of these 76 patients, 46 (60.5%) underwent surgery as a part of their treatment regimen for acute IE. The patient demographics are listed in Table 1. Although no age or racial differences were found between the 2 groups, those in the surgical group were more likely to be male (P = .016).

Infection Site
The infection site was identified in 23 nonsurgical (76.7%) and 46 surgical (100%) patients. Native valve involvement (43% vs 83%, P = .020) and left-sided lesions (27% vs 54%, P = .001) were more common in the surgical group. The presence of congenital heart disease was not significantly different between the 2 groups (P = .172). The specific infection sites are listed in Table 2.

Causative Organisms
Positive culture data were obtained from 46 patients (60.5%): 17 nonsurgical (56.7%) and 29 surgical (63.0%) patients. *Staphylococcus aureus* and *Streptococcus* infections were the most common isolated organisms, occurring in 18 (23.7%) and 17 (22.4%) patients, respectively. Of those with *S aureus* IE, methicillin-sensitive *S aureus* was present in 13 patients and methicillin-resistant *S aureus* was present in 5. In the subgroup analysis, *S aureus* was the most common organism in the surgical group (3% vs 37%, P ≤ .001) and *Streptococcus* occurred more frequently in the nonsurgical group (33% vs 15%, P = .019). No significant differences were seen in the rates of coagulase-negative *Staphylococcus* infection (13% vs 9%, P = .270). Other organisms included *Escherichia coli* in 1 surgical patient (2.2%), *Serratia marcescens* in 1 nonsurgical patient (3.3%), and *Enterococcus faecalis* in 1 nonsurgical patient (3.3%).

Surgical Data
The most common indication for surgery was acute, severe valvular insufficiency (22 patients, 47.9%). Of those, 9 patients (40.9%) also had evidence of concomitant ventricular dysfunction. Septic embolization was present in 20 patients (43.5%) at surgery and was the primary surgical indication in 12 patients (26.1%). Of those 12 patients, cerebrovascular embolization occurred in 10, pulmonary embolization in 1, and renal embolization in 1. Persistent intracardiac vegetation, despite appropriate medical management, was present in 12 patients (26.1%). In these patients, the vegetations involved the tricuspid valve with less than severe insufficiency in 5, the right ventricle with less than severe tricuspid insufficiency in 4, the right atrium with persistent positive blood culture findings in 2, and the right atrium with evidence of inferior vena cava obstruction in 1. Vegetations were documented in 39 patients (51.3%), with 25 (64.1%) having a vegetation of 10 mm or greater and 14 (35.9%) having a vegetation less than 10 mm. The differences in disease characteristics between the 2 groups are listed in Table 3.

Timing of Surgery
The median interval to surgery was 3.0 days (IQR, 1.0-7.5 days) from the diagnosis of IE. Although most
patients (35, 76%) underwent surgery within 7 days of the diagnosis, a significant number (25, 54%) underwent surgery within 3 days. The factors associated with surgery within 3 days from diagnosis are listed in Table 4. On multivariate analysis, infection due to *S aureus* was a significant factor (odds ratio, 4.8; 95% confidence interval, 1.3-17.8) for surgery within 3 days from diagnosis.

**Follow-up and Outcomes**

The median patient follow-up period for the entire cohort was 4.5 years (IQR, 1.3-7.1 years). No significant difference was seen in the median follow-up between the nonsurgical group (median, 4.5 years; IQR, 1.3-17.8) and surgical group (median, 5.2 years; IQR, 2.8-7.9 years) and surgical group (median, 3.8 years; IQR, 1.1-6.5 years; *P* = .995).

The all-cause mortality of the entire cohort during the follow-up period was 7.9% (6 patients). Although overall mortality was lower in the surgical group (6.5% vs 10.0%), this difference did not reach statistical significance (*P* = .583). The 1-, 5-, and 10-year survival of the nonsurgical group was 96% ± 4%, 89% ± 7%, and 81% ± 10%, respectively. Comparatively, survival among the surgical group was 98% ± 2%, 90% ± 8%, and 81% ± 11% at 1, 5, and 10 years, respectively (log-rank *P* = .866; Figure 1).

A single 30-day operative death (2.1%) occurred in a 15-year-old boy with mitral valve IE. He had been undergoing active chemotherapy for acute lymphocytic leukemia when he acutely experienced a catastrophic neurologic insult due to septic cerebral embolization. He arrived at our institution in a moribund state but was taken to the operating room on admission day 2 in an effort to remove any additional source of embolization. However, he was declared brain dead on admission day 11, despite all resuscitative measures.

Of the remaining 5 deaths, 2 were associated with IE. An infant with a structurally normal heart experienced worsening mitral valve insufficiency secondary to IE. Because of the patient’s size at the development of infection, immediate surgical therapy was deferred. The patient successfully completed a 6-week antibiotic course but died 8 months after discharge. Of the other 3 deaths, 1 was related to mitral valve insufficiency.

OR, Odds ratio; CI, confidence interval.
later of complications from congestive heart failure as a valvular surgical evaluation was being performed. The second IE-related mortality occurred in a surgical patient 7.1 years after aortic valve replacement owing to an initial episode of IE. He presented with IE of the prosthetic aortic valve but succumbed to overwhelming sepsis soon after presentation.

No evidence of postoperative septic embolization was found. The recurrence rate of IE was not significantly different statistically, occurring in 2 nonsurgical patients (6.7%) and 1 surgical patient (2.2%; \( P = .330 \)). The recurrence of IE was significantly associated with increased mortality (hazard ratio, 6.4; 95% confidence interval, 1.1-36.3).

Of the 38 surgical patients with native valve involvement, 19 (50.0%) required valve replacement and 19 underwent successful native valve repair. Of the 19 patients requiring valve replacement, 12 involved the aortic position, 5 the mitral position, and 2 the right ventricular outflow tract. In the aortic position, an aortic homograft was used in 8 patients, a pulmonary autograft (Ross procedure) in 3, and a bioprosthetic valve in 1. In the mitral position, a mechanical valve was used in 4 patients and a composite valve in 1. In the right ventricular outflow tract, a valved conduit was used in both patients. Valve replacement was not significantly associated with mortality (\( P = .435 \)). Although no repeat valve replacements occurred in the surgical group, 3 nonsurgical patients (10.0%) required valve replacement (\( P = .029 \)) within the follow-up period after completing their medical therapy course.

No significant differences were found in mortality (\( P = .562 \)) or overall valve replacement (\( P = .469 \)) between patients who had surgery more than 7 days versus within 3 days from diagnosis.

**DISCUSSION**

The continuously changing epidemiology and characteristics of pediatric IE demands an evolving understanding of treatment options and effect on outcomes to improve associated morbidity and mortality. In the present study, 1 of the largest reported pediatric surgical cohorts for IE, we found that early surgery can be successfully performed in children with high rates of native valve repair and low rates of recurrence and mortality.

Although no pediatric-specific surgical guidelines for acute IE exist, established American Heart Association adult guidelines have been endorsed by the American Academy of Pediatrics. We found that the indications for surgery at our institution generally mirror those identified in adult guidelines, including ventricular dysfunction, acute valvular insufficiency, and uncontrolled infection. These findings are similar to a recent, multicenter review describing the surgical indications of children with congenital heart disease who developed IE. In addition, we found a number of other factors associated with surgical intervention, including the presence of left-sided vegetations, \textit{S aureus} infection, and a history of at least 1 previous embolization event. These factors might represent an institutional bias toward an aggressive surgical approach to minimize embolization risk owing to a high incidence of \textit{S aureus} infection in our cohort. However, additional appropriately designed comparative studies would need to be conducted to adequately evaluate the suitability of these indications.

Recent studies of adult populations have demonstrated improved survival when surgery for IE was performed early in specific patient subgroups. This benefit has been attributed to several factors, including the early management of a reversible cause of ventricular dysfunction, minimizing embolization risk, and aggressive treatment of \textit{S aureus}. This is an important consideration owing to the highly virulent nature of \textit{S aureus}, because these children are more likely to present with significantly advanced disease, including aortic root involvement, valvular damage, and abscess formation. In addition, changing trends in the epidemiology have shown that \textit{S aureus} has become 1 of the most common pathogens responsible for IE, which was reflected in our findings. Owing to the risk of advanced disease, our institutional practice is to take children with \textit{S aureus}-related IE to the operating room as soon as possible with the goal of minimizing the risk of disseminated disease and septic embolization and improving the possibility of native valve repair.

To date, information is limited concerning the effects of surgical timing on the outcomes in children. Although Nomura and colleagues demonstrated that surgical intervention during the active phase of infection might be
a necessary adjunct to antibiotic therapy in certain sub-
groups, the timing of the surgical intervention was not de-
scribed. Recently, Hickey and colleagues demonstrated that surgery occurring within 1 week of diagnosis of a cere-
brovascular accident due to septic embolization was safe.
However, that study was limited by the small patient popu-
lation in the cerebrovascular accident group and lacked a de-
scription of the interval to surgery from the diagnosis of IE.

In the present study, we found that most surgical patients underwent surgery within 7 days of diagnosis of IE and that one half of those patients underwent surgery within 3 days. Surgery within 3 days was significantly associated with ventricular dysfunction or *S. aureus* infection on univariate analysis and *S. aureus* infection on multivariate analysis. As a result of our aggressive surgical approach, 50% of pa-
tients underwent native valve repair, no postoperative em-
bolization events occurred, and mortality was low.

Previous reports have described greater morbidity and mortality in patients with ventricular dysfunction or *S. au-
reus* infection. Thus, early surgical involvement in these
children might have an advantageous role in their treatment
by minimizing the risk of embolization and abscess forma-
tion in the case of staphylococcal infection and potentially reverse the cause of ventricular dysfunction. We have dem-
onstrated early surgery can be safely performed in children, with low postoperative mortality and acceptable medium-
to long-term outcomes.

**Study Limitations**

Although the present study is 1 of the largest pediatric surgical cohorts with regard to IE, it was limited by its single-center retrospective design of a moderate number of patients. Although all available data were used in the sta-
tistical analyses, the negative endpoints described in the present study might have resulted from a lack of statistical power. Therefore, it would be difficult to exclude the possi-
bility of a type II error, and additional studies with greater numbers of patients are required to establish negative associations.

The design of the present study prevented a direct compari-
son between the surgical and nonsurgical groups owing
to an inherent selection bias. Attempts to alleviate this bias
using statistical methods, such as propensity scoring, were
not possible owing to the small study size. Thus, the find-
ings of the present study should be interpreted in the context
of the descriptive nature of the data. Although the present
study was not designed to directly compare the outcomes of early surgery with those of late surgery or medical ther-
apy alone, it has demonstrated that early surgery can be per-
formed safely and effectively in children. Finally, signifi-
cant associations with respect to surgical indications and timing represent the practice of our large, US tertiary-
care children’s hospital and might not be generalized to
dissimilar institutions or locations.

**CONCLUSIONS**

Early surgical intervention in children with acute IE can
be performed safely with excellent results. The benefit of early surgery might play a significant role in the treatment of IE caused by *S. aureus* by minimizing the risk of progres-
sive cardiac disease and septic embolization. Furthermore,
early surgery, in conjunction with appropriate antibiotic
therapy, can be performed in children safely, with excellent
results, even in the acute phase of infection. Additional
study is required to better understand the overall indications
for surgery and those who might benefit most from early surgical intervention.
