thrombectomy may be excluded for these critically ill patients, although an emergency transplant remains an option.

CONCLUSIONS

Coronary occlusion as a result of aortic thrombosis is a rare but catastrophic complication of venoarterial ECMO as a bridge to delayed surgery for post-MI VSR. During this highly thrombogenic period, LV pulsatility and aortic valve opening must be strictly preserved and heparin therapy closely monitored. A heart transplant should be considered in the most severe cases when the risk of surgical repair is considered too high.

Mitral valve repair using autologous leaflet tissue as neochordae

Peter Benedikt, MD, MSc,a Christian Punzengruber, MD,b Laszlo Milassin, MD,a and Choi Keung Ng, MD,c Wels and Innsbruck, Austria

Since the introduction of standardized mitral valve repair,1 techniques have continuously evolved. Different methods are known to avoid or minimize tissue resection, like artificial chordal replacement or autologous pericardial leaflet augmentation.2 We report the case of a patient who underwent mitral valve repair 20 years ago using autologous tissue leaflet as neochordae according to a technique of Gregory and colleagues.3

CLINICAL SUMMARY

A 52-year-old man was admitted to our hospital for severe regurgitation with prolapse and chordal rupture at the posterior leaflet of a myxomatous mitral valve. Coronary angiography results and left ventricular function were normal.

SURGICAL TECHNIQUE

After median sternotomy cardiopulmonary bypass was set up by bicaval cannulation. Heart arrest was achieved with cold crystalloid cardioplegia. The mitral valve was exposed via right atriotomy through the interatrial septum. After mitral valve analysis, which depicted a flail leaflet in P2 and accompanying prolapse in P1 and P3, the valve was repaired by using a strip of autologous tissue of the posterior mitral leaflet as neochordae.

Two parallel incisions at a distance of 4 mm were set in the prolapsing segment of the posterior mitral leaflet.
beginning 2 mm from the annulus and ending 3 mm before the free edge (Figure 1, A). This excised strip was anchored to the papillary muscle with pericardial pledget-supported 5-0 polypropylene sutures (Figure 1, B). The incision in P2 was closed with continuous 5-0 polypropylene sutures. Annuloplasty was performed with a rigid prosthetic ring (Carpentier 32 mm, Edwards Lifesciences, Irvine, Calif). After weaning from cardiopulmonary bypass intraoperative transesophageal echocardiography revealed a fully competent mitral valve.

The postoperative course was uneventful and the patient was discharged 10 days after surgery.

In the meantime the patient was repeatedly admitted to the hospital because of hypertension and atrial flutter that was first seen 2 years after surgery, a pacemaker implantation to correct bradycardia and atrial fibrillation 10 years ago, and circumflex stenting because of single vessel disease 6 years ago.

The 20-year echocardiography follow-up confirmed an effective mitral valve repair functioning with the strip of autologous tissue as neochordae (Figure 2). Regurgitation was trivial and left ventricular function was slightly globally reduced as a result of left atrial dilatation.

DISCUSSION

With the introduction of standardized surgical techniques mitral valve repair has become reproducible and prevalent. Leaflet resection followed by either annuloplasty or sliding leaflet plasty has been the gold standard to repair posterior leaflet disorder and has demonstrated excellent long-term results. Leaflet prolapse with limited residual tissue is best addressed with conservative resection or chordal reconstruction.4

Instead of midsize to large leaflet tissue resection, chordal reconstruction avoids the sacrifice of leaflet tissue for the sake of a larger coaptation surface. Furthermore, by preserving posterior leaflet tissue, the anatomic and dynamic relationship is maintained, allowing the physiologic distribution of forces and stresses on valve components and the left ventricle.5 These facts apply to autologous reconstruction, which has the advantage of avoiding additional extraneous material.

Gregory and colleagues3 described a technique using autologous valve tissue as neochordae to reconstruct a disorder of the anterior leaflet. We report the case of a patient with a characteristic pathology of the posterior leaflet that was repaired using this technique 20 years ago. A current echocardiograph conducted on this patient demonstrates that the application is fully competent, even after 20 years.

In our experience, 3 patients with different anterior and posterior leaflet pathologies have undergone operation successfully with the technique introduced by Gregory and colleagues3 and achieved good short- and midterm results.

Autologous reconstruction is applicable for long-term durability and is not cost-prohibitive. Autologous chordal replacement provides an accurate alternative technique, broadening the surgical armamentarium in mitral valve repair.
