Surgical aortic valve replacement (SAVR) is a challenge in patients with porcelain aorta, because the calcified aorta is difficult to manage. Studies have reported significant risks of stroke and mortality in these patients.1

The conventional treatment for aortic stenosis is SAVR, but the advent of transcatheter aortic valve replacement (TAVR) has expanded treatment options to operable and higher-risk patients. Because TAVR does not require cardiac arrest, the need to clamp the aorta is avoided, but this treatment has been reserved for high-risk patients with suitable anatomy.2

Since the advent of TAVR, we have encountered an increase in patients with severe aortic stenosis in whom SAVR was attempted but aborted because of intraoperative discovery of porcelain aorta. These patients were referred for definitive treatment and possible TAVR.

Both SAVR and TAVR were performed in these patients. The objectives are to characterize patients, describe treatment options, and assess outcomes.

PATIENTS AND METHODS

From 2001 to 2013, 19 patients with a history of aborted SAVR and severe aortic valve dysfunction underwent definitive aortic valve replacement with SAVR (n = 7) or TAVR (n = 12) at the Cleveland Clinic. The mean age at the time of operation was 74 ± 11 years. Aortic valve dysfunction included severe aortic stenosis (n = 16), regurgitation (n = 1), or both (n = 2). The mean preoperative aortic valve gradient was 51 ± 18 mm Hg (SAVR: 46 ± 8 mm Hg, TAVR: 56 ± 16 mm Hg). Table 1 summarizes the patient characteristics for both groups.
The median interval between aborted aortic valve replacement at the outside facility and definitive procedure with SAVR or TAVR at the Cleveland Clinic was 9.6 months. In 10 patients (53%), off-pump coronary artery bypass grafting was performed at the time of aborted aortic valve replacement, and the sternotomy was closed without additional procedures in the remaining 9 patients. Data were collected from chart review and augmented with Social Security Death Index when available. Descriptive statistical analyses are used to present variables for the study. The study was approved by the institutional review board of Cleveland Clinic, with patient consent waived.

**Surgical Aortic Valve Replacement**

The surgical approach was via redo sternotomy (median, 6; minimally invasive, 1). Bioprosthetic valves were used in 5 patients, and a mechanical valve was used in 2 patients. Two patients in this group also had bicuspide aortic valve. The median prosthetic valve size was 25 mm. The aorta was not clampable in 4 patients because of severe calcification of the ascending aorta, and hypothermic circulatory arrest with retrograde brain perfusion was used. The ascending aorta was replaced in all 4 patients. In the other 3 patients, the ascending aorta was relatively spared of calcification near the brachiocephalic artery, and it was possible to crossclamp the aorta in that region to avoid circulatory arrest. In no patients was there adequate healthy aorta for both clamping and cannulating. Right axillary artery cannulation was applied in all 7 patients. Nine concomitant procedures were performed in 6 patients for coexisting cardiac disease. These included ascending aortic replacement (n = 4), coronary bypass (n = 3), mitral valve repair (n = 1), and tricuspid valve repair (n = 1). One patient with severe radiation heart disease required 4 procedures along with SAVR.

**Transcatheter Aortic Valve Replacement**

This technique was used in 12 patients. The approach was transfemoral in 5 patients. The other 7 patients had severe peripheral arterial disease prohibiting this approach. These were treated using transapical (n = 6) or transaortic (n = 1) access. Balloon-expandable valves (Sapien, Edwards Lifesciences, Santa Rosa, Calif) were used in all patients in this group. Valve sizes were 23 mm in 4 patients and 26 mm in 8 patients.

In 1 patient in this group, intraoperative paravalvular leak developed that was managed with placement of an additional valve-in-valve. Another developed hemodynamic instability and required temporary use of an intra-aortic balloon pump.

**RESULTS**

The mean postoperative gradients were 13 ± 4 mm Hg (SAVR: 14 ± 3, TAVR: 14 ± 4 mm Hg). At a median follow-up of 16 months, there was no operative mortality, paravalvular leak, stroke, renal failure, or reoperation for bleeding. There were 5 late deaths, 4 in the TAVR group and 1 after SAVR. The patient who died post-SAVR had lung cancer and died approximately 1 year postoperatively of pneumonia associated with the lung cancer. The remaining 4 deaths in the TAVR group all occurred in patients with multiple comorbidities. One patient died 5 months post-TAVR of persistent heart failure due to diastolic dysfunction and severe mitral and tricuspid regurgitation despite a well-functioning TAVR. One patient died of complications related to respiratory failure 2 months post-transaortic TAVR at a long-term care facility. She had a recent history of lung cancer treated with radiation on continuous oxygen and required a tracheostomy postprocedure. One patient died 17 months post-TAVR of complications related to a chronic gastrointestinal bleed, and 1 patient died 3 years later of acute on chronic renal failure despite a well-functioning TAVR valve. No patients required valve-related reintervention during late follow-up.

**DISCUSSION**

The conventional approach for treatment of severe aortic stenosis is SAVR, but the procedure can be technically challenging when the aorta is severely calcified, and this also increases the risk of stroke.1-3 Studies have reported a mortality of up to 14% in these patients.3 This experience demonstrates that both SAVR and TAVR can be safely performed at a valve center specializing in the treatment of high-risk patients. TAVR expands options by providing a clampless alternative for replacing the aortic valve in patients with calcified aorta who may be too high risk for SAVR.4-6 Use of auxiliary artery cannulation with or without hypothermic circulatory arrest may facilitate SAVR in these patients who are otherwise candidates for aortic valve replacement.

The choice of procedure type was based on a thorough preoperative assessment to determine the operative risk, anatomic feasibility, and need for additional procedures for cardiac comorbidities. SAVR was the preferred choice in patients with multiple cardiac comorbidities requiring additional procedures, such as coronary bypass, ascending aortic replacement, and mitral or tricuspid valve repair. SAVR also was more often performed during the earlier period of this experience when TAVR was not as readily available. Conversely, TAVR was preferred in patients...
with isolated aortic valve disease and suitable anatomy who did not require additional procedures and those who were too high risk for an open operation.

Previous studies have reported a high incidence of stroke with SAVR in patients with porcelain aorta. In the current experience, this was not observed in any of the patients. At the Cleveland Clinic, we routinely use axillary artery cannulation and have a low threshold to use this technique in patients with aortic disease. This strategy has been shown to decrease the risk of stroke by minimizing manipulation of the atherosclerotic ascending aorta.3,7-9 The axillary artery cannulation was used in all patients who were treated with SAVR in this experience.

Most patients treated with SAVR (n = 4/7) had a diffusely calcified proximal aorta involving the root, ascending aorta, and often extending into the arch and beyond. Careful evaluation of the proximal aorta using 3-dimensional reconstructions was critical in the preoperative planning to determine whether it was possible to crossclamp the aorta (Figure 1). If not, the repair was performed using hypothermic circulatory arrest or a TA VR approach. In patients who are otherwise at a reasonable risk, replacing the ascending aorta in this setting has been shown to decrease the risk of stroke.3 The circulatory arrest time is short in these patients because it is essentially used for just a single open distal anastomosis. We have not tended to use antegrade brain perfusion in these patients because it has not been shown to be superior for short periods of circulatory arrest; in addition, the arch branch vessels are typically diseased in these patients, and we have not wanted to manipulate them. In 3 patients (n = 3/7), the aortic calcification was found to be patchy on computed tomography, and it was possible to successfully clamp the ascending aorta where it was relatively spared. In these patients, ascending repair was not performed, but axillary cannulation was still used.

In comparison, the patients who were treated with TAVR were older with significant comorbidities and presented with severe aortic valve stenosis and porcelain aorta, but they did not require other cardiac intervention. Five of these patients had coexisting coronary artery disease, but had undergone off-pump coronary artery bypass grafting at the time of prior aborted sternotomy or had been adequately revascularized several years before presenting to the Cleveland Clinic. TAVR expands the options in high-risk patients, many of whom are not candidates for SAVR. In this experience, the median Society of Thoracic Surgeons score was 8 for the patients who underwent TAVR. Although these procedures were all feasible, proper patient selection is critical to successful long-term outcomes. Two of the 5 late deaths occurred within the first 6 months postprocedure. One death was due to respiratory failure in a patient with severe lung disease who had transaortic delivery through a mini-J sternotomy. One late death was due to heart failure related to severe atrioventricular valve dysfunction and diastolic dysfunction. In retrospect, these patients may have been better relegated to medical therapy only as “cohort C” patients.

The choice of delivery for TAVR was based on iliofemoral vessel anatomy. The transfemoral approach was preferred when the anatomy was suitable; otherwise, alternative approaches were used. TAVR offers a distinct advantage in patients with porcelain aorta by alleviating the need for aortic clamping, but it is a complex operation requiring a multidisciplinary skill set.10 Many patients with porcelain aorta have vasculopathy, and so only 5 of 12 were amenable to transfemoral delivery. TAVR and SAVR should be considered complementary options for these complex cases, and the best option is determined by the heart team.

CONCLUSIONS
Both SAVR and TAVR at a tertiary care center are safe and effective treatment options in patients with a severely calcified aorta. Procedure selection may be tailored to individual patients on the basis of anatomy, comorbidities, and perceived operative risk. Preferably, severe aortic disease should be identified and imaged in detail before the aortic valve procedure.
Individualized treatment strategies for patients with aortic valve disease and porcelain aorta

Scott A. LeMaire, MD

The presence of porcelain aorta, defined as severe circumferential calcification of the aorta (Figure 1), substantially increases the complexity and risk associated with the treatment of aortic valve (AV) disease. The unique report by Idrees and colleagues focuses on a series of 19 patients who were referred for treatment after an attempt at open surgical AV replacement (AVR) was abandoned due to the unanticipated discovery of porcelain aorta. Importantly, this is a contemporary series that began in 2001 and includes the period just before the availability of transcatheter aortic valve replacement (TAVR) devices. The report indicates that excellent early results can be achieved when an individualized approach is applied at an experienced center. Notably, no patients died within 30 days and no patients experienced stroke. Although the report focuses on patients referred after aborted AVR, the results and their implications are relevant to all patients with porcelain aorta and AV disease. Their experience highlights that a successful individualized treatment strategy hinges on several key decision points.

WHETHER TO PERFORM ANY PROCEDURE AT ALL

The first decision point, whether or not to proceed with any AVR intervention, is perhaps the most challenging. In the series by Idrees and colleagues, there were 2 deaths within 6 months after TAVR; both deaths were due to comorbid conditions, and the authors acknowledge that nonoperative management may have been a better choice for these patients. As articulated by Miller, the line between utility and futility for TAVR has not yet been clearly defined. Improving our ability to identify those patients who are unsuitable for either open AVR or TAVR remains an extremely important focus of investigation. A recent analysis of Placement of Aortic Transcatheter Valve (PARTNER) trial results to identify predictors of poor outcomes is an excellent step in this direction.

WHETHER TO PERFORM OPEN AVR OR TAVR

Once the decision has been made to proceed with an intervention, the next decision centers on whether to perform open AVR or TAVR. In the series by Idrees and colleagues, this decision was largely driven by whether additional cardiac procedures were needed; patients with aneurysmal ascending aorta, multivalve disease, or
