Giant, pedunculated right atrial thrombus formation after surgical atrial septal defect repair

Sayqa Arif, MRCP, Dincer Aktuerk, MRCS, and David J. Barron, FRCS, Birmingham, United Kingdom

Despite advances in percutaneous catheter-based interventions, surgical repair with direct suture or a patch is still required for large secundum and other types of atrial septal defect (ASD), with excellent results and a low mortality. Although rare, thrombotic complications secondary to atrial thrombus formation after surgical ASD repair have been previously reported. There is, however, no consensus regarding the optimal postoperative antiplatelet or anticoagulation regimen. We report a case of a giant right atrial (RA) mass unrelated to the ASD patch. A review of the literature and the clinical management of postoperative atrial thrombi are discussed.

CLINICAL SUMMARY
A 20-year-old man came to the hospital with palpitations and breathlessness. Results of clinical examination were unremarkable. Initial investigations, including an electrocardiogram and a chest radiograph, demonstrated no abnormalities. Eleven months previously, the patient had undergone primary surgical repair of a large secundum ASD with a bovine pericardial patch. The patient was advised to take low-dose (75 mg once daily) aspirin for 6 months after that operation. Transthoracic echocardiographic scans performed before hospital discharge and at 3-month routine clinical review revealed no evidence of residual leak and no significant cardiac abnormality.

On admission, transthoracic echocardiography demonstrated a large, spherical, pedunculated mass in the RA, the etiology of which was uncertain. Transesophageal echocardiography (Figure 1) confirmed a mobile mass attached to the anterior aspect of the superior vena cava at its entrance into the RA. The mass was highly mobile, suspended by a thin, linear attachment, and prolapsing into the tricuspid valve (Figure 1, A). Because of the size of the mass and the fact it was freely mobile, emergency surgery was performed. Intraoperative findings revealed a large spherical 6-cm mass arising from a thin, fibrous stalk attached to the lateral wall of the RA at the junction of the superior vena cava and the RA (Figure 2). The pedicle was not related to the septum or the ASD patch. Histologic evaluation of the mass revealed a bland ball thrombus, with no evidence of neoplasia. It was postulated that the original nidus for the thrombus was the tip of the central venous cannula inserted at the time of the original surgery, which allowed gradual, concentric layering of thrombus with time. A thrombophilia screen was undertaken and demonstrated no evidence of hypercoagulability. The patient made an uneventful recovery and received anticoagulation with warfarin for 6 months. Follow-up at 3 months after the removal of the mass demonstrated no evidence of intracardiac thrombus recurrence. Further transthoracic echocardiographic follow-up is planned in 6 months and annually thereafter.

DISCUSSION
Postoperative intra-atrial thrombus after surgical ASD closure has been observed as late as 8 years after the original
Thrombus is usually reported as being related to the patch and is often associated with established atrial fibrillation or flutter. In most situations, cardiac surgery has been performed for excision of the mass and its exact nature determined by histopathologic examination. In the case presented here, the thrombus was unrelated to the patch and occurred in an otherwise healthy young man with no evidence of atrial arrhythmia. This case emphasizes the need for routine echocardiographic follow-up. Guidelines recommend regular echocardiographic surveillance after surgery, usually at 24 hours, 1 month, 6 months, 1 year, and then at regular intervals.\footnote{Visconti KJ, Bichell DP, Jonas RA, Newburger JW, Bellinger DC. Developmental outcome after surgical versus interventional closure of secundum atrial septal defect in children. \textit{Circulation}. 1999;100(19 Suppl):III145-50.}

There is no consensus regarding postoperative antiplatelet or anticoagulation therapy. Our institutional practice is treatment with single antiplatelet therapy for 6 months for all patients who have undergone surgical ASD patch repair.

Review of the literature demonstrates that there are no data regarding incidence of thrombus formation after surgical ASD repair, and it is therefore difficult to define the extent of the problem. Data are largely derived from isolated case reports. After this diagnosis of intracardiac thrombus, we elected to provide anticoagulation for our patient with a vitamin K antagonist. The duration of anticoagulation is to be determined by resolution of thrombus on subsequent serial echocardiographic scans. Others have also raised the possibility of commencing anticoagulation therapy in patients after patch ASD repair.\footnote{Yılmaz M, Güreltop Y, Erdoğan F. Right atrial thrombus following closure of an atrial septal defect. \textit{Heart}. 2003;89:726.}

Accepting that there is little guidance in the literature as to the optimal regimen after surgical ASD repair, it may be reasonable to consider antiplatelet therapy for several months in patients undergoing patch ASD repair. If subsequent intracardiac thrombus formation occurs despite antiplatelet therapy, anticoagulation is warranted for some period afterward, until resolution of the thrombus occurs. This subject merits further attention and discussion in view of the potential serious consequences of intracardiac thrombus development.

Cor triatriatum dexter: A rare cause of myocardial infarction and pulmonary embolism in a young adult

Syed T. Hussain, MD, Kwabena Mawulawde, MD, Robert D. Stewart, MD, and Gösta B. Pettersson, MD, PhD, Cleveland, Ohio

Cor triatriatum dexter (CTD) is an extremely rare congenital cardiac anomaly in which the right atrium (RA) is divided into 2 chambers by a membrane; it is caused by persistence, instead of the usual regression, of the right valve of the sinus venosus and is frequently associated with right-sided cardiac abnormalities. CTD has varying clinical manifestations, depending on the degree of partitioning or septation of the RA, from completely asymptomatic to severe right-sided heart failure. We present a case of CTD in a young adult presenting with myocardial infarction and pulmonary embolism who eventually underwent successful surgical excision of the membrane and removal of RA and tricuspid valve thrombus.

CLINICAL SUMMARY

A 22-year-old woman presented with acute-onset left-sided chest pain and shortness of breath and was diagnosed with a small subsegmental pulmonary embolism and placed on enoxaparin. Lower-extremity Doppler was negative. Coagulation studies, including Factor V Leiden mutation, performed because of her family history of pulmonary embolism, were all negative. Echocardiography revealed severe RA enlargement, a thickened tricuspid valve, and a large atrial septal defect with right-to-left shunt. She had a history of asthma and peripheral cyanosis, and she had suffered an inferior-wall myocardial infarction with...
