Minocycline pigmentation of the cardiac valves and aorta in a 29-year survivor of liver transplant

A 34-year-old man who received a liver transplant 29 years ago was incidentally found to have a 6.5-cm asymptomatic aortic root aneurysm with mild aortic insufficiency. Given the aneurysm size, a valve-sparing aortic root replacement was recommended. The patient's medical history included congestive heart failure, chronic renal failure, biliary atresia, Crohn's disease, and chronic minocycline use for acne.

Operative findings were extensive discoloration of the aortic valve cusps, aorto-mitral curtain into the mitral valve (Figure 1), and media of the ascending aorta. The aortic valve was enlarged and stretched with mild calcification of aortic valve annulus. The right coronary sinus wall was thinned out and ventriculized. Because of the quality of the valve and dysfunction of other organs, an aortic root replacement was performed with a 29-mm Freestyle porcine aortic valve (Medtronic Inc, Minneapolis, Minn) with the ascending aorta with a 26-mm Dacron graft.

The patient had an unremarkable postoperative course and was discharged 6 days later. Pathology revealed patches of hemorrhage and myxoid degeneration of the aortic valve leaflet with subtle pigmentation on Fontana–Masson stain. The aorta and aortic root had no significant abnormality except for atherosclerosis with no dissection (Figure 2, A–C). The liver report found chronic rejection and no fibrosis with Trichrome stain.

Black cardiac tissue pigmentation has been reported rarely.1–4 Two causes are minocycline use or alkaptonuria. No case reports were found of black cardiac tissue pigmentation in liver transplant recipients, although minocycline may cause liver failure.5 Black pigmentation caused by minocycline seemingly does not affect cardiac valve functionality.2,3 A valve-sparing aortic root replacement was not chosen because of the patient’s chronic liver dysfunction, high-risk coagulopathy after a long cardiopulmonary bypass, and uncertainty of survival and “black” aortic valve durability. The bioprosthesis selection was large enough for future once to twice valve-in-valve transcatheter aortic valve replacement. Mechanical valve and Coumadin use were not recommended because of frequent liver biopsy.

Minocycline is a semisynthetic tetracycline used for the treatment of a wide range of various infections. Although minocycline has proven to be a very safe, and more recently comes under the spotlight because of its cardioprotective potential,1 various drug-specific side effects have been reported (ie, tissue pigmentation, systemic lupus erythematosus-like syndrome, autoimmune hepatitis, and polyarteritis nodosa).2 Pigment deposition in human tissue can occur in association with long-term minocycline therapy. Most of the pigmentations involve the skin, thyroid gland, sclera, nails, and bones.3 Pigmentation rarely is reported in heart valves.

So far, there are 3 clinical reports, including our experience, and 1 cadaveric report that describe minocycline-induced heart valve pigmentation.4-7 In this issue of the Journal, Cohen and colleagues8 added another experience.
