We encountered a patient with misleading computed tomographic (CT) findings that resembled those of acute type A aortic dissection (AD).

A 60-year-old man with pulseless electrical activity was transferred to our emergency department. Extracorporeal membrane oxygenation (ECMO) was quickly initiated. The patient’s echocardiogram showed severely impaired left ventricular function, with no cardiac output from the left ventricle. After the initiation of ECMO, the CT revealed that the mid to distal portion of the ascending aorta and proximal aortic arch resembled those of acute type A AD (Figure 1). We made a diagnosis of acute type A AD with

**Central Message**

Aortic dissection–like computed tomography findings in a patient with mechanical circulatory support after left coronary ostial occlusion can mislead clinicians when determining treatment strategy.

See Editorial Commentary page 1640.

ostial occlusion of the left main coronary artery and planned emergency replacement of the ascending aorta, coronary artery bypass grafting, and initiation of central ECMO or implantation of a left ventricular assist device.

Acute AD was not, however, observed under direct vision. Preoperative transesophageal echocardiography (TEE) could not exclude AD because of the “blind spot” of TEE. Epiaortic echography revealed 2 blood flow layers in the ascending aorta and aortic arch. The support flow from the femoral artery stagnated at the aortic valve, because no blood emerged from the nonfunctioning left ventricle (Figure 2 and Video 1). The misleading findings on CT may be attributable to blood stagnation. We performed coronary artery bypass grafting and left ventricular assist device implantation. The patient is currently alive with left ventricular assist device support. We recognized negative CT findings inconsistent with acute AD, such as an intact sinus of Valsalva and an intimal flap–like low-density borderline in the aortic arch, which lacked continuity with both the proximal and distal sides, and positive findings for acute myocardial infarction, such as severe calcification of the left coronary artery (Figures 3 and 4).1,2 Although the visualization of the distal ascending aorta and aortic arch is impaired relative to CT, the diagnostic sensitivity of TEE for AD is almost 100%. Even in patients in hemodynamically unstable condition, TEE can be performed in an operating room. Additional multimodality imaging including modified TEE thus could have helped to avoid a false-positive diagnosis in a patient on ECMO.3

VIDEO 1. The video shows intraoperative epiaortic echography. Two layers of blood flow can be seen; one slows blood flow to the patent right coronary artery and arch vessels, and the other shows stagnant blood from the retrograde perfusion of percutaneous cardiopulmonary support. CT, Computed tomography. Video available at: http://www.jtcvsonline.org/article/S0022-5223(17)32474-1/fulltext.
