Atrial contractility and fibrotic biomarkers are associated with atrial fibrillation after elective coronary artery bypass grafting

ABSTRACT

Objective: New-onset postoperative atrial fibrillation is common after cardiac surgery. Less has been reported about the relationship among fibrosis, inflammation, calcium-induced left atrial and right atrial contractile forces, and postoperative atrial fibrillation. We sought to identify predictors of postoperative atrial fibrillation.

Methods: From August 2016 to February 2018, we evaluated 229 patients who had preoperative sinus rhythm before elective primary coronary artery bypass grafting. Of 229 patients, 191 maintained sinus rhythm postoperatively, whereas 38 patients developed atrial fibrillation. Preoperative tissue inhibitor of metalloproteinase-1, pentraxin-3, matrix metallopeptidase-9, galectin-3, high-sensitivity C-reactive protein, growth differentiation factor 15, and transforming growth factor-β were measured. Clinical and echocardiographic findings (tricuspid annular plane systolic excursion for right heart function) and calcium-induced force measurements from left atrial and right atrial–derived skinned myocardial fibers were recorded.

Results: Patients with atrial fibrillation were older (P = .001) and right atrial areas (P = .0001), and had decreased tricuspid annular plane systolic excursion (P = .001). Levels of matrix metallopeptidase-9 and pentraxin-3 were decreased (P < .05), whereas growth differentiation factor 15 was increased (P = .001). We detected lower left atrial force values at calcium-induced force measurements 5.5 (P < .05), 5.4 (P < .01), and 5.3 to 4.52 (P = .0001) and right atrial force values at calcium-induced force measurements 5.0 to 4.52 (P < .05) in patients with postoperative atrial fibrillation. Multivariable analysis showed that advanced age (P = .033), decreased left atrial force value at calcium-induced force measurement of 5.5 (P = .033), enlarged left atrial (P = .013) and right atrial (P = .081) areas, and reduced tricuspid annular plane systolic excursion (P = .010) independently predicted postoperative atrial fibrillation.

Conclusions: Advanced age, decreased left atrial force value at calcium-induced force measurement of 5.5, enlarged left atrial and right atrial areas, and reduced tricuspid annular plane systolic excursion were identified as independent predictors for postoperative atrial fibrillation. (J Thorac Cardiovasc Surg 2020;159:515-23)
New-onset postoperative atrial fibrillation (POAF) is a common complication after cardiac surgery with an incidence of 10% to 65%.\(^1\) It is associated with poor short- and long-term outcomes, including increased risk for stroke and mortality.\(^1,3\) Advanced age has been described as an independent predictor of POAF.\(^1\) In patients at risk requiring coronary artery bypass grafting (CABG), there is an unmet need of point-of-care predictors of POAF.\(^2\)\(^,\)\(^4\)

Current understanding suggests that there is a highly interdependent metabolic, electrical, and contractile pathophysiology predominantly in atrial tissue.\(^5\)\(^,\)\(^6\) Rapid-rate arrhythmias are triggered because of the reduced availability of calcium.\(^9\)\(^,\)\(^11\)

Some evidence suggests preexisting atrial fibrotic remodeling is present in some patients, which may lead to sustained conduction abnormalities.\(^12\) In persistent atrial fibrillation (AF), potential mediators were oxidative stress, fibrosis, advanced age, inflammation, and pressure and volume overload.\(^13\)\(^,\)\(^15\)\(^,\)\(^16\) Recent work demonstrated the association of these mediators with specific biomarkers (eg, pentraxin 3, tissue inhibitor of metalloproteinase 1 [TIMP-1], matrix metalloproteinase 9 [MMP-9], high-sensitivity C-reactive protein, transforming growth factor-\(\beta\), galectin-3, and growth differentiation factor 15 (GDF-15)).\(^10\)\(^,\)\(^11\)\(^,\)\(^20\)\(^-\)\(^23\) but this link remains poorly characterized. It is plausible that inflammation induces POAF or that AF itself manifests inflammation and is merely a marker of increased risk.\(^13\)\(^,\)\(^15\) Similar inconsistencies exist regarding cardiac contractility. Although the impact of AF on cardiac contractility has been extensively investigated, the question of decreased preoperative contractility as a precondition for developing POAF remains underreported, especially in human tissue. Likewise, echocardiographic functional parameters such as tricuspid annular plane systolic excursion (TAPSE) for right heart function as a predictor of POAF remains unknown. Altogether, the relative paucity of articles and inconsistencies linking potential mechanisms inflammation, fibrosis, cardiac contractility, and right heart function with the development of POAF contributes to uncertainty.

In this study, we evaluated in detail the clinical, experimental, and echocardiographic data that predispose to the development of POAF in patients undergoing primary CABG procedures. We collected all clinical and experimental parameters (eg, blood samples and intraoperative specimens of resected left atrial appendages [LAAs] and right atrial appendages [RAAs]). We analyzed the contractile properties of the left and right myofilaments of these patients and compared the results of patients who had postoperative sinus rhythm (SR) versus those with POAF.

**MATERIALS AND METHODS**

The present study is a prospective longitudinal cohort study examining consecutive patients with and without POAF. A total of 286 patients were initially planned to include in the study. Because of intraoperative contraindications, experimental problems, incomplete data, and denied permission to participate, we finally analyzed 229 patients with complete data sets. We included 229 patients in SR undergoing elective primary CABG between August 2016 and February 2018. A total of 191 patients maintained SR for the duration of the postoperative period, and 38 patients developed POAF (Figure 1).

All patients provided written informed consent. The Ethics Committee of the University Würzburg approved the study. All consented patients scheduled for elective, isolated CABG were included. All patients underwent on-pump CABG procedures and had resection of their LAA and RAA, which were then sent immediately to the laboratory for further investigation. We excluded patients with myocardial infarction within the previous 48 hours, patients with associated intracardiac procedures, emergency cases, patients with infectious diseases (eg, tuberculosis, human immunodeficiency virus, or hepatitis), patients with reoperations or minimally invasive procedures, or patients with incomplete data. We included all patients presenting in SR upon admission and excluded those with a history of AF (Figure 1).

Our registry contains retrospective preoperative and perioperative data modeled after the STS National Database criteria.\(^24\)\(^,\)\(^25\) Electrophysiologically documented AF and clinically diagnosed AF were included in the clinical documentation for the diagnosis of POAF and reported on the basis of the standardized definition established by the 2014 American Association for Thoracic Surgery guidelines\(^22\) and The Society of Thoracic Surgeons Practice guidelines and database.\(^20\)

American Society of Echocardiography. 26,27 Intraoperative data and occurrence of POAF were documented for every patient.

Experimental Set-up

We measured the calcium-induced force of LA and RA skinned human fibers. The skinned fiber approach removes all membrane-dependent and receptor-mediated processes and excludes drug effects such as β-blocker. All patients underwent careful LAA and RAA resections (Video 1). The RAA was resected for venous cannulation of extracorporeal circulation. The LAA was resected for stroke prevention immediately after aortic cross-clamping and under cardiopulmonary arrest. All patients were operated on cardiopulmonary bypass using a single-clamp approach with antegrade Buckberg blood cardioplegia with an initial dose for 4 minutes and repetitive doses every 20 minutes for 2 minutes.

Samples were immediately placed in cold, oxygenated Krebs–Henseleit solution (50 mL; amounts in mmol/L: NaCl 118.07, C6H12O6 5, KCl 4.7, NaHCO3 25, KH2PO4 1.2, MgSO4·7H2O 20, C4H8N3O5PNa2 2, C3H4N2·H2O 68.08, C4H10O2S2·154.25, and C10H14N5O13 P3 Na2 380.35) with 30 mmol/L 2,3 butanedione monoxime (BDM). BDM (Sigma Aldrich Chemie GmbH, Steinheim, Germany) is a myosin inhibitor that prevents contraction and minimizes cellular trauma during transport. In preparation for skinned fiber measurements, trabeculae were excised and exposed to a preparation solution containing Triton-X (amounts in mmol/L: C3H4N2 20, NaCl 10, C4H12N2O10 4, NaHCO3 2, MgCl2·6H2O 3, CaCl2·2H2O 2, MgCl2·6H2O 5, C4H10O2S2·2H2O 3, Na2PO4·7H2O 3, 30 mmol/L BDM). BDM (Sigma Aldrich Chemie GmbH, Steinheim, Germany) for “skinning” of the sarcolemma, a process requiring 24 hours.

Next, the trabeculae were washed with freshly prepared solution (without Triton-X) followed by careful preparation of the fibers. The sarcolemma was removed, and single bundles (0.3 × 3 mm) were isolated for calcium-induced force measurement (pCa). Both ends of the myofilaments were grasped with 2 forceps apart, of which 1 forcep is connected to a force transducer that recorded changes in the length of the suspended myofilaments in millinewtons. The fibers were then immersed in 12 varying calcium solutions, starting with the lowest calcium concentration. The filament lengths were lowered into the solution, avoiding any undue stretch. Changes in fiber length were recorded, and the fibers were subsequently prestretched in a relaxation solution (in mmol/L: C4H8N3O5PNa2 20, C4H10O2S2·154.25, and C10H14N5O13 P3 Na2 380.35) to a sarcomere length of 2.0 μm. After achieving a prestretched steady state and adjusting the measurement curve to zero, the experimental
cycle was repeated with ascending calcium concentrations. Fibers remained immersed in the calcium solutions for 15 minutes to achieve maximal forces at each calcium concentration. To move to the next calcium concentration, chloride dihydrate (CaCl₂·2H₂O, 147.02 mN) was added to the solution. Three myocardial fibers of every patient sample (LAA and RAA) were excised, and the experimental cycle was performed once with every fiber. The calcium concentrations (pCa) are given as negative decadic logarithms, a dimensionless quantity. The calcium concentrations in ascending order were pCa 7.0, 6.5, 6.0, 5.75, 5.5, 5.4, 5.3, 5.2, 5.1, 5.0, 4.75, and 4.52. Concentrations ranging from 10⁻⁷ to 10⁻⁵ mol/L are considered physiologic. Concentrations greater than pCa 5.0 are supraphysiologic, but useful for eliciting maximal force capacity.

### Statistical Analysis

Metric variables are given as means and medians, and the range of dispersion is given as standard deviations and quartiles. Categoric data are shown as absolute and relative frequencies. Metric data were tested for normal distribution with the Kolmogorov–Smirnov test. For testing pairs of independent and normally distributed variables, Student’s t test was used. Before applying the t test, the homogeneity of variances was ascertained with Levene’s test. If homogeneity was not present, Welch’s t test was performed. Not normally distributed and independent variances were tested with the Mann–Whitney U test. Normally distributed metric variables were analyzed with the Student t test. All categoric variables were analyzed with the chi-square test and Fisher exact test. As a post hoc test, the standardized residuals were defined and interpreted as follows. Candidate variables considered for the multivariable analyses were those detected by univariate models as having a >.05 or suggestive trend toward association (P = .05-.10) predictive of POAF; retention of variables in the multivariable model was set at P < .05. To discriminate independent risk factors, multivariable modeling was performed with methods of stepwise selection, with entry/stay criteria of 0.05/0.1 using a likelihood-ratio test, with groups and candidate variables all competing for entry into a final
model predicting POAF. Univariate and multivariable analyses were performed in the same manner to identify predictors of POAF. We performed a 2-sided significance test for all tests. All estimates are provided with 95% confidence intervals. All diagrams were created with SPSS for Windows, Version 24 (SPSS Inc, Chicago, Ill).

RESULTS

Demographic data are depicted in Table 1. Patients with POAF were older (73 ± 7 years vs 68 ± 10 years, \(P = .001\)). The POAF group had a higher prevalence of arterial hypertension (84% vs 75%, \(P = .04\)) and presented with higher preoperative creatinine (1.36 ± 0.14 vs 1.09 ± 0.47, \(P = .03\)) with decreased preoperative glomerular filtration rate (67.2 ± 22.82 vs 76.57 ± 23.12 mL/min, \(P = .02\)). LA area was larger in patients with POAF (27.88 ± 7.21 cm² vs 19.46 ± 4.97 cm², \(P = .0001\)), as was RA area (21.84 ± 8.76 cm² vs 15.13 ± 4.16 cm², \(P = .0001\)). TAPSE was decreased in the POAF group (18.61 ± 3.85 vs 23.29 ± 3.76, \(P = .001\)). Regarding biomarkers for inflammation and fibrosis, MMP-9 was decreased in patients with POAF (274.48 ± 325.14 pg/mL vs 875.68 ± 375.78 pg/mL, \(P = .029\)). Conversely, GDF-15 was increased in the POAF group (1277.69 ± 594.72 vs 1010.64 ± 1308.79, \(P = .0001\)). Preoperative NT-proBNP was increased in patients with AF (1867.47 ± 120.48 vs 1407.38 ± 4181.01, \(P = .0001\)). Pentraxin-3 was decreased in the POAF group (2419.80 ± 663.11 vs 3135.33 ± 204.03, \(P = .04\)).

There were no statistically significant differences in the duration of the CABG procedure and in the number of venous grafts among patients (Table 2). The use of arterial grafts was lower among patients with POAF (1.1 ± 0.93, 1.60 ± 0.86, \(P = .01\)).

In LAA (Table 3 and Figures 2-4), we found lower force values in patients with POAF at the following calcium concentrations: pCa 5.5 (0.34 ± 0.19 mN vs 0.41 ± 0.23 mN, \(P = .04\)), pCa 5.4 (0.45 ± 0.20 vs 0.56 ± 0.26 mN, \(P = .008\)), pCa 5.3 (0.52 ± 0.22 vs 0.67 ± 0.29 mN, \(P = .0001\)), pCa 5.2 (0.60 ± 0.24 vs 0.79 ± 0.33 mN, \(P = .0001\)), pCa 5.1 (0.67 ± 0.25 vs 0.88 ± 0.35 mN, \(P = .0001\)), pCa 5.0 (0.68 ± 0.27 vs 0.90 ± 0.37 mN, \(P = .0001\)), pCa 4.75 (0.75 ± 0.28 vs 0.98 ± 0.38 mN, \(P = .0001\)), and pCa 4.52 (0.75 ± 0.29 mN vs 0.97 ± 0.38 mN, \(P = .0001\)). Likewise, in RAA (Table 3), we found a trend toward reduced force values for patients with POAF at calcium concentrations of pCa 5.2 (0.51 ± 0.25 vs 0.60 ± 0.28 mN, \(P = .07\)) and pCa 5.1 (0.57 ± 0.27 mN vs 0.67 ± 0.30 mN, \(P = .062\)). The difference became significant between groups at pCa with reduced force values in patients with POAF: pCa 5.0 (0.57 ± 0.28 mN vs 0.68 ± 0.32 mN, \(P = .04\)), pCa 4.75 (0.63 ± 0.30 vs 0.76 ± 0.34 mN, \(P = .03\)), and pCa 4.52 (0.62 ± 0.31 mN vs 0.75 ± 0.26 mN, \(P = .03\)).

Multivariable analysis revealed the following parameters as independent predictors for new-onset POAF after CABG: LAA force value at pCa 5.5 (\(P = .033\)), LA area (\(P = .013\)), RA area (\(P = .081\)), TAPSE (\(P = .010\)), and advanced age (\(P = .033\)) (Table 4).

There was no in-hospital death. New-onset POAF occurred in 7 patients (18%) on postoperative day 1, increasing to 15 patients (40%) on day 2 and 13 patients (35%) on day 4 and decreasing to 3 patients (7%) on day 5. Length of stay was longer in the POAF group (13.23 days [median 11 ± 3] vs 10.87 days [median 10 ± 2]), but this difference was not significant (data not shown).

DISCUSSION

This study demonstrates that preoperative patients with SR who develop AF after CABG have significantly reduced preoperative contractile capacity in the LA and RA tissue as measured in the skinned fiber model (Figure 5). We chose the skinned fiber approach because the myocardial contractile apparatus is a valid surrogate for intrinsic myocardial function, independent of membrane-dependent processes and proteins.22,23

Previous work has proposed several pathophysiological models of POAF, such as alterations in refractoriness or
local reentry pathways, probably caused by mechanisms of reperfusion injury, such as local inflammation and insufficient cardioplegic protection of the atria during cardiopulmonary bypass. Recent work has focused on atrial-specific mechanisms resulting in early contractile dysfunction and metabolic remodeling. Multiple studies have shown the negative impact of AF on atrial contraction, but the data are scant on the effect of new-onset AF in skinned human fibers. Reduced force capacity has been demonstrated histologically and on echocardiography solely for chronic and persistent AF. However, there are no data linking new-onset AF and the
cardiac contractile capacity of atrial myofilaments, partly due to inconsistent experimental techniques and measurements of functional parameters. Depressed force values are assumed to arise from the downregulation of L-type Ca\(^{2+}\) channels and increased Ca\(^{2+}\) influx via sodium-calcium exchangers. The resultant reduction of maximal force recruitment and impaired calcium sensitivity seem to be related to new-onset AF. Force values are reportedly reduced by approximately 70\% compared with patients in SR. These prior observations corroborate with our results. However, these studies do not differentiate between left and right myofilament function. We observed a significant reduction of force values in cardiac myofilaments of both sides of the heart. Likewise, Belus and colleagues observed significant reductions in maximal tension rates, passive tension, and increased calcium sensitivity in chronic AF. Other studies report comparable results in chronic AF, usually with small sample sizes and in RA or LA tissue, but not both.

We also observed significant differences in the serum levels of preoperative MMP-9, GDF-15, pentraxin-3, and NT-proBNP. On multivariable analysis, these biomarkers did not influence the risk of POAF (Table 4 and Figure 5). Previous work revealed that MMP-9 is increased in patients with ischemic heart disease and associated with vascular remodeling and atherosclerotic plaque formation. Other studies showed that increased levels of TIMP-1, an important inhibitory regulator of MMPs, MMP-9, and NT-proBNP are associated with the development and progression of AF. MMP-9 as an inflammatory biomarker is also strongly associated with hypertension and renal disease. Likewise, in our experience with patients with POAF, we observed decreased MMP-9 levels. In those patients, we also found higher prevalence for arterial hypertension, decreased renal function and increased TIMP-1 levels (Table 1). The latter may have contributed to the decreased MMP-9 levels.

Other studies showed that GDF-15 is a strong predictor for mortality in patients with AF. GDF-15 has been described as a marker of cellular stress, senescence, and inflammation, whereas NT-proBNP is known to signify myocardiocyte stress and dysfunction. Considerable data have shown that age is a strong predictor for AF. Our POAF study population was older and had elevated levels of NT-proBNP.

The LA has so far been supposed to predict AF recurrence in patients after catheter ablation, and most recently

also identified as a potential predictor for POAF. This work supports our observation of increased LA area in patients developing AF.

On echocardiography, we found significantly reduced TAPSE values in patients with POAF compared with patients with AF. This is an important finding, considering that current guidelines are virtually silent on the effects of AF on echocardiographic assessment of right heart function. AF, in our observation, has a definite impact on TAPSE as a measure of right ventricular systolic function compared with patients with SR. This is plausible, because AF and right ventricular dysfunction frequently coexist in heart failure with preserved ejection fraction and AF is strongly associated with reduced RA and right ventricular function. We found significantly reduced force values at higher calcium concentrations in RA fibers. This was equally true for supraphysiologic calcium concentrations and corresponds to the assumption that contractile reserve is reduced in patients with AF (Figure 5).

A novel and surprising finding was the enlarged RA area in patients with POAF. RA area index was recently identified as a strong independent predictor of hospitalization due to clinically significant supraventricular arrhythmias in patients with pulmonary hypertension. However, there exists no information about the predictive value of RA area in patients with AF (without pulmonary hypertension). Our binary regression analysis shows that RA area is an independent predictor for POAF. From a clinical standpoint, closer attention to echocardiographic parameters such as atrial areas or TAPSE in patients undergoing elective CABG procedure may be warranted. Of note, but of less practical importance, we also identified an experimental parameter capable of independently predicting the new-onset POAF. We observed that the force value of LA tissue at a calcium concentration (pCa) of 5.5 was significantly decreased in patients with AF. Of note, this is a relatively low calcium concentration, representing a baseline state of the myofilament before calcium levels increase and trigger contraction (Figure 5). To our knowledge, this has not been described in the literature.

The observation of significantly reduced experimental force values in patients with POAF, combined with the clinical finding of normal LVEF on echocardiogram, suggests that patients with experimentally observed decreased contractile function are predisposed for the development of POAF despite having normal LVEF. These findings might help identify surgical cardiac patients at risk for POAF. Patients presenting with enlarged LA and RA areas, reduced TAPSE, and advanced age are at higher risk for developing POAF and might benefit from closer surveillance in the postoperative course or from high potassium or magnesium levels, preventing the occurrence of POAF. Further studies need to confirm our observations in larger cohorts.

Study Limitations
Several limitations of this study must be noted. First, 286 patients undergoing elective CABG were initially screened for participation in our study, but 229 patients were finally enrolled with complete clinical and experimental data sets. Excluded patients were those with intraoperative contraindications of atrial resection, such as fragile tissues (n = 19), incomplete data (n = 20), withdrawn consent (n = 3), and tissues with technical problems during experimentation (n = 13). Although complete medical histories were collected, prior sporadic episodes of AF in these patients cannot be completely excluded. Although to date, this study is one of the largest of its kind, the sample size is still inadequate to draw meaningful conclusions. Untoward influences of other clinical parameters, such as the higher prevalence of arterial hypertension in the AF group or larger atrial sizes, are always possible and might affect contractility values. Furthermore, operator-specific treatment of the tissue samples with possible damage to the trabeculae cannot be excluded, although harvesting protocols were designed with a high degree of standardization. Some of our results seem to conflict with the current understanding, such as increased MMP-9 and pentraxin-3 values in the SR group, and must be reevaluated in a larger population. Despite the nature of our study, our initial observations may serve as a catalyst for future mechanistic and randomized prospective studies examining our hypothesis.

CONCLUSIONS
In preoperative patients with SR who develop AF after elective CABG, LA and RA contractility are significantly reduced compared with patients without POAF. The force value of LA myofilaments at pCa of 5.5 appeared to be an independent predictor for the development of POAF. Several other independent parameters seem relevant to predict the development of AF: advanced age, LA area, RA area, and TAPSE.
