Commentary: A tale of the left ventricle

Kristopher B. Deatrick, MD, and Sunjay Kaushal, MD, PhD

The historical outcomes of the Ross or Ross-Konno operation in centers of excellence remain outstanding, and it remains the criterion standard surgical repair for infants, children, and adolescents with aortic stenosis or regurgitation or with left ventricular outflow tract obstruction.1-3 Despite the inherent advantages of the Ross or Ross-Konno operation, including the potential for somatic growth, most long-term outcome studies have centered on the deterioration of the aortic autograft or pulmonary homograft. Another potential long-term complication yet to be determined is the growing concern for electromagnetic dysynchrony, given the high prevalence of bundle branch block and prolonged QRS duration in patients undergoing Ross and Ross-Konno operations.4 Once electromagnetic dysynchrony is identified, cardiac resynchronization therapy readily treats ventricular dyssynchrony, with positive remodeling of the left ventricle, which may affect long-term outcomes.

In this issue of Journal, Schäfer and colleagues5 present their experience to evaluate and compare the extent of electrical and mechanical dysynchrony with cardiac magnetic resonance imaging after Ross and Ross-Konno operations. In their study, they determined that patients undergoing both the Ross and Ross-Konno operations had normal biventricular functional status but reduced left ventricle longitudinal strain. In addition, both groups demonstrated increased right-left inter-ventricular dyssynchrony relative to the control group, but only the Ross-Konno group had increased septal left intraventricular dyssynchrony. More importantly, the global left ventricular intramechanical dysynchrony strongly correlated with QRS duration. The significance of the relationship between these findings and meaningful clinical outcomes need further evaluation; however, patients who have undergone either the Ross or Ross-Konno operation may have chronic increased afterload, independent of the consequences of the left ventricular function or the autograft and pulmonary graft function.

As a pilot study, this thoughtful evaluation of ventricular function by Schäfer and colleagues5 raises critical and interesting questions. Although there are changes in left ventricular strain and function, in addition to dyssynchrony, in patients who have undergone Ross and Ross-Konno operations relative to control patients, the use of normal, healthy patients as a control group leads to the question of whether these findings are indicators of the primary pathology. In other words, negative left ventricular remodeling may still be present long after the relief of left ventricular outflow obstruction or the correction of aortic stenosis or regurgitation, even after surgical intervention. In any circumstance, for young patients, particularly neonates and infants, there are currently no other suitable surgical options. Although electrical dyssynchrony has been shown to lead to mechanical dyssynchrony and adversely affect function in adults, it is uncertain what the degree of reduced left ventricular strain, as measured by magnetic resonance imaging, will portend for these patients in the future.6 The finding that this metric of left ventricular strain is more predictive of mortality than left ventricular ejection fraction for adult patients with acute decompensated heart failure, however, suggests that these patients may have a greater risk of reduced long-term outcomes.7 We must be cautious, however, in extrapolating data from a different surgical population group of adults with a fundamentally different pathophysiology for predictions related to patients who have undergone Ross and Ross-Konno operations. Finally, although it is a single-institution, retrospective experience, this study raises the additional question of when to intervene when left ventricular global longitudinal strain is present in these patients.
This study of Schäfer and colleagues\textsuperscript{5} adds to the understanding of the complex interplay of cardiac electrical physiology, myocardial coordination, and function in patients who have undergone Ross and Ross-Konno operations. The next step will determine when an intervention with cardiac resynchronization therapy will need to occur according to the degree of left ventricular strain abnormalities present on magnetic resonance imaging. Regardless, studying these patients who have undergone Ross and Ross-Konno operations for continued abnormalities in left ventricular performance will be critical for their long-term outcomes.
