Commentary: You have to be able to walk the walk if you want to have a successful proximal aortic procedure

Ansar Hassan, MD, PhD

Frailty has been defined in terms of an accumulation of deficits that results in a loss of physiological reserve. When applied to an elderly population, this concept allows for the differentiation of biological age from chronological age, with biological age serving as a more sensitive predictor of survival. In recent years, the negative impact of frailty on outcomes following cardiac surgery has become the subject of numerous publications, with cardiac surgeons attempting to find ways to defrail patients in advance of their cardiac procedure.

To date, few studies have examined the effect of frailty in patients undergoing thoracic aortic surgery. Ganapathi and colleagues used a frailty score composed of 6 elements—age, body mass index, anemia, hypoalbuminemia, history of stroke, and total psoas volume—to identify patients at risk for worse short- and long-term outcomes following thoracic aortic surgery. Gomibuchi and colleagues used a similar frailty score composed of 7 elements, including the psoas muscle index, to identify patients at risk for late mortality following surgery for acute type A aortic dissection.

In their study presented in this issue of the Journal, Hobbs and colleagues set out to determine the effect of frailty on postoperative outcomes following proximal aortic surgery using a singular measure: 5-m gait speed. The primary outcome of interest was a composite of in-hospital mortality, renal failure, prolonged ventilation, and discharge to a location other than home. A cutoff of 0.83 m/s was used to separate slow from normal gait speed. Following risk-adjustment, slow gait speed was found to be an independent predictor of worse in-hospital outcomes.

In a continuing effort to better understand the frailty phenotype, this study provides valuable insight into the considerable weight that 5-m gait speed alone has in being able to predict adverse outcomes following proximal aortic surgery. Despite the small sample size, 5-m gait speed testing was associated with a 2.34-fold greater likelihood of experiencing the primary outcome of interest. This was even after adjusting for the EuroScore II risk score, which already includes “poor mobility” as a patient-related factor.

Admittedly, this study has some limitations, the most pronounced of which is a significant number of eligible patients who did not undergo 5-m gait speed testing. A comparison of patients who underwent the test with those who did not showed a greater comorbid disease burden in the latter group. The effect of this result on the ultimate study findings is not clear, and as such, the authors’ final results should be interpreted with caution.

Having said that, this study is important for 2 reasons. First, it supports the role of prehabilitation in mitigating the risk faced by patients with slow preoperative gait speed. A comparison of patients who underwent the test with those who did not showed a greater comorbid disease burden in the latter group. The effect of this result on the ultimate study findings is not clear, and as such, the authors’ final results should be interpreted with caution.

CENTRAL MESSAGE
In patients undergoing proximal aortic surgery, 5-m gait speed provides a valuable assessment of risk and offers an opportunity for prehabilitation whereby such risk may be mitigated.
at-risk patients using a singular and easily obtainable measure is of inestimable value.
