Scoring systems serve a common goal to standardize the classification of complex conditions to improve decision-making. When properly built, they can predict outcomes and assist in patient stratification for clinical trials. In the field of coronary artery disease (CAD), the SYNTAX (Synergy Between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery) score has become widely used to classify the severity of coronary lesions, and it has been integrated into a culture that guides the choice of revascularization strategy between percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG).

When first introduced, the SYNTAX score was never intended for use as a predictive tool but rather to objectively quantify the severity of CAD in enrolled patients. It was only post-hoc analyses of the SYNTAX cohort that demonstrated the score’s ability to predict major adverse cardiac and cerebrovascular events in patients undergoing PCI. Although surgery was overall superior in terms of major adverse cardiac and cerebrovascular events, there was no apparent benefit of CABG versus PCI in the low (SYNTAX score <22) and intermediate (SYNTAX score >22 and ≤33) tertiles.

These findings have perpetuated a narrative that favors PCI in low SYNTAX scores and CABG in high SYNTAX scores, even though in the original SYNTAX trial, there was no relationship between surgical outcomes and CAD complexity and in fact risk decreased with increasing scores. Subsequent trials comparing CABG and PCI have further supported that surgical outcomes are poorly correlated with SYNTAX score and that prognosis is better related to patient clinical profile and procedural variables.

In this meta-analysis comparing PCI and CABG, Gaudino and colleagues hypothesized that the benefit of CABG versus PCI would not vary substantially according to SYNTAX scores. To prove their hypothesis, the authors performed a sensitivity analysis using ratios of incidence rate ratios to generate interaction effect estimates and compare outcomes between each SYNTAX score tertile. When combining the results from SYNTAX and other large trials, (including FREEDOM [Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease] and NOBLE [Nordic-Baltic-British Left Main Revascularization]), they found that the incidence rate ratio was significantly in favor of CABG in low, intermediate, and high SYNTAX score groups (1.25 [1.02-1.54], 1.48 [1.30-1.69], and 1.39 [1.18-1.63], respectively). This emphasizes that the narrative of PCI being indicated in the lower tertiles is fallacious, since surgery is superior in all tertiles. SYNTAX probably only indicated to us that PCI risk in the highest tertile was arguably prohibitive.

CENTRAL MESSAGE
While the SYNTAX score can distinguish patients with a prohibitive risk for percutaneous coronary intervention, it has no role in predicting poor outcomes after coronary artery bypass grafting.
These results are not surprising, since we know that the SYNTAX score (a surrogate for coronary disease complexity) lies within the causal pathway for PCI and late outcomes, and behaves as a mediator of outcomes. In contrast, there is no direct relationship between the SYNTAX score and outcomes after CABG because this mediating effect is absent. In fact, the complexity of the coronary artery lesions has little effect on the quality of the revascularization because surgeons bypass the diseased portions of the vessel. Surgeons approach the conundrum of coronary insufficiency not by unravelling the knot but by distal bypass rendering coronary complexity moot in the same manner as Alexander the Great handled the Gordian Knot.
